CSF = cerebrospinal fluid.

TABLE 41–2. Differentiating Botulism from Guillain-Barré Syndrome

	<i>Botulism</i>	<i>Guillain-Barré Syndrome</i>	<i>Miller Fisher Variant of Guillain-Barré Syndrome</i>
Fever	Absent (except in wound botulism)	Occasionally present	Occasionally present
Pupils	Dilated or unreactive (50%)	Normal	Normal
Ophthalmoplegia	Present (early)	May be present (late)	Present (early)
Paralysis	Descending	Ascending (classically, but not necessarily)	Descending
Deep tendon reflexes	Diminished	Absent	Absent
Ataxia	Absent	Often present	Present
Paresthesias	Absent	Present	Present
CSF protein	Normal	Elevated (late)	Elevated (late)

CSF = cerebrospinal fluid.

Infant Botulism

First described in California in 1976, several thousand cases of infant botulism have now been confirmed across the world.^{10,65,68} Interestingly, 95% of these cases are reported in the United States.^{46,98} Although infant botulism is reported from approximately half of the states in the United States and all inhabited continents except Africa,⁴⁶ 50% of reported cases originate from California, Utah, Pennsylvania, and New Mexico.¹⁵⁰ In California, aggressive surveillance and educational efforts have been practiced since 1976, which may help to explain the disproportionate distribution of reported cases.⁸

Infant botulism is the most common form of botulism in the United States, and virtually all cases are due to BoNT type A or B. Affected children are younger than 1 year (median of 15 weeks) and characteristically have normal gestation and birth. The first signs of infant botulism are constipation; difficulty with feeding, sucking, and swallowing; feeble cry; and diffusely decreased muscle tone (“floppy baby”).³⁶ The hypotonia is particularly apparent in the limbs and neck. Ophthalmoplegia, loss of facial grimacing, dysphagia, diminished gag reflex, poor anal sphincter tone, and respiratory failure are often present, but fever does not occur. Mydriasis is typical, and hypotension may occur. The differential diagnosis of infant botulism initially includes salt and water depletion, failure to thrive, sepsis, and a viral syndrome. Because the toxin in infant botulism is absorbed gradually as it is produced, the onset of clinical manifestations may be less abrupt than in severe cases of food-borne botulism, which are caused by large amounts of preformed toxin absorbed over a brief period of time.

Infant botulism may result from ingestion of *C. botulinum* organisms in food or following the inhalation or ingestion of organism-laden aerosolized dust. A number of factors determine a child’s susceptibility to development of botulism. Although bile acids and gastric acid in the GI tract may inhibit clostridial growth in older children and adults, gastric acidity is reduced in the infant during the first few months of life.⁸¹ Also, some infants may be deficient in immunologic mechanisms for spore control, resulting in a permissive environment for spore germination and toxin development within their GI tracts and subsequent gut absorption. Approximately 70% of infant botulism cases occur in breastfed infants, even though only 45% to 50% of all infants are breastfed. Formula-fed infants are rapidly colonized by *Coliforme* spp, *Enterococcus* spp, and *Bacteroides* spp, which may inhibit *C. botulinum* proliferation; conversely, the absence of these typical organisms in breastfed infants may facilitate *C. botulinum* multiplication.⁶⁵

Epidemiologic studies in Europe have found that ingestion of honey was associated with 59% of cases of infant botulism.¹⁵ When *C. botulinum* spores were isolated from honey implicated in cases of infant botulism, the same toxin type was isolated from the infant and, as expected, no preformed toxin was isolated from the honey.¹⁰ Honey is the only food generally considered likely to be a risk factor for infant botulism,¹⁰ although a 2001 report from the United Kingdom implicated a milk formula in the development of infant botulism.⁹⁴ It is possible that pollen and nectar carried by worker bees results in contamination of honey with spores of *Clostridia* found in soil.⁹² In addition, the oxidative metabolism of *Bacillus alvei*, another common contaminant of honey, may promote spore germination by creating an anaerobic microenvironment.⁸⁹

Previous studies suggested a correlation between the presence of both *C. botulinum* organisms and toxin and sudden infant death syndrome (SIDS).^{8,130} However, in a prospective study of 248 infants with SIDS, *C. botulinum* was not found on stool culture of any of the children.²⁸

Cases of infant botulism must be managed in the hospital, preferably in a pediatric intensive care unit for at least the first week, when the risk of respiratory arrest is greatest. In one study, approximately 80% of children with botulism

required intubation for reduced vital capacity, and 25% of these children had frank respiratory compromise.¹¹⁶ In a group of 57 affected infants, 18 days to 7 months of age, managed during the decade ending in the mid-1980s, 77% were intubated and 68% required mechanical ventilation. In the subsequent decade, investigators from the same institution found that 37 of 60 (62%) infants required endotracheal intubation (for a mean duration of 21 days).⁴ The apparent decrease in intubations and complications was ascribed to better understanding of disease progression and closer observation of patients. However, a similar study at another institution revealed that 13 of 24 (54%) infants admitted between 1985 and 1994 required ventilatory support, compared to 15 of 20 (75%) infants admitted in the subsequent decade.¹³⁹ All but one patient in this study required nasogastric feeding. Airway complications of intubation such as stridor, granuloma formation, and subglottic stenosis are common, yet tracheotomy is infrequently required.³ The survival rate in infant botulism is approximately 98%.¹¹⁷

Wound Botulism

Wound contamination previously was considered an uncommon cause of botulism. The first case of wound botulism was not reported until 1943. The classic presentation of wound botulism is that of a patient injured in a motor vehicle who sustains a deep muscle laceration, crush injury, or compound fracture treated with open reduction. The wound typically is dirty and associated with inadequate débridement, subsequent purulent drainage, and local tenderness, although in some cases the wound appears unremarkable. Four to 18 days later, cranial nerve palsies and other neurologic findings typical of botulism may appear.⁸⁷ Other manifestations characteristic of food-related botulism, such as GI symptoms, usually are absent.

In wound botulism, fever may be prominent and associated with abscess, sinusitis, or other tissue infection presumed to harbor the clostridial organisms. Although some patients may require management for wound-related problems, in other cases the wounds appear clean and uninfected. Recognition of botulism as a potential complication of wound infections is essential for appropriate early and aggressive therapy.

Between 2001 and 2009, the CDC identified between 22 and 30 cases of wound botulism each year, except in 2006 when 45 cases were identified.³⁸ In 2010, there were 17 cases reported, and in 2011, 13 cases. BoNT type A accounted for all cases of wound botulism in 2011.³⁸ Use of heroin, particularly subcutaneous injection (“skin-popping”) of black tar heroin, is associated with an increased number of wound botulism cases.^{42,100,112,148} This association appears to be related, at least in part, to the physical characteristics of black tar heroin such as its viscosity, its potential to facilitate anaerobic growth and spore germination, and its ability to devitalize tissue or inhibit wound resolution.¹⁹ Wound botulism is also reported in association with subcutaneous,¹⁰⁴ intravenous,¹³³ and intranasal^{71,107} cocaine use. The first case of wound botulism with BoNT type E was reported in 2007, affecting a drug user in Sweden.¹³

In a small series of parenteral drug-using patients with botulism in New York City, the most prominent symptoms were dysphagia, dysarthria, and dry mouth. BoNT type A toxin was detected in the serum of one patient, and in another patient *C. botulinum* was isolated from an abscess. In four other drug abusers with clinically comparable presentations, CDC investigators were not able to find any organism or toxin in serum, stool, or skin lesions.⁷⁷

Adult Intestinal Colonization Botulism

Although GI colonization is the typical pathogenetic mechanism responsible for infant botulism, it is rare in adults. Prior to 1997, only 15 cases were reported.^{59,85} Patients invariably have anatomic or functional GI abnormalities. Risk factors favoring organism persistence and *C. botulinum* colonization include achlorhydria (surgically or pharmacologically induced), previous intestinal surgery, and probably recent antibiotic therapy. These factors may compromise the gastric and bile acid barrier, gut flora, and motility, thus allowing spore germination, altered bacterial growth, and toxin development.

Cases of adult infectious botulism have occurred in patients after ileal bypass surgery and Crohn disease,⁵⁹ jejunoileal bypass for obesity,^{55,84} gastroduodenostomy,⁸⁴ vagotomy and pyloroplasty,⁸⁴ and necrotic volvulus.⁷⁶ In such hosts, botulism can result from the ingestion of food contaminated with *C. botulinum* organisms and no preformed toxin, with intraluminal elaboration of toxin occurring in vivo.⁴⁵

In one case of adult intestinal colonization botulism, a high concentration of endogenously produced antibody to toxin type A was identified.⁵⁹ This finding highlights a distinct characteristic of this form of botulism, because endogenous antitoxin immunity does not develop in patients with food-borne botulism.¹¹⁴

Iatrogenic Botulism

Botulinum toxins are used therapeutically in the treatment of a variety of disorders. Three preparations of BoNT type A are available in the United States: onabotulinumtoxinA (Botox), abobotulinumtoxinA (Dysport), and incobotulinumtoxinA (Xeomin). BoNT type B is available as rimabotulinumtoxinB (Myobloc). All are approved by the FDA for treatment of cervical dystonia, and all three formulations of BoNT type A are approved for cosmetic purposes. OnabotulinumtoxinA and

incobotulinumtoxinA are also approved by the FDA for treatment of blepharospasm. Additionally, onabotulinumtoxinA is approved for treatment of strabismus, upper limb spasticity, chronic migraine, severe axillary hyperhidrosis inadequately managed by topicals, and detrusor overactivity associated with a neurologic condition. These xenobiotics are thought to exert their therapeutic effect in most cases by temporarily weakening those muscles whose overactivity results in the clinical condition. Doses range widely depending on the size of the muscles to be treated, the degree of overactivity, and the commercial preparation of the toxin. The injected toxin blocks the local neuromuscular junction by inhibiting release of acetylcholine. The “chemodenervated” muscles recover within 2 to 4 months as nerve transmission is restored through sprouting of new nerve endings and formation of functional connections at motor endplates,^{2,114} necessitating repeated injections of BoNT for prolonged clinical efficacy.

Doses of BoNT are measured in functional units corresponding to the median intraperitoneal lethal dose (LD₅₀) in female Swiss-Webster mice weighing 18 to 20 g.⁹⁹ The units of each marketed pharmaceutical are distinctly different and may lead to inadvertent overdosing.¹⁴³ The potential for confusion may be substantial when switching between products, because their relative potencies are quite different.^{95,110,119} Attempts to establish precise lethal doses of BoNT are complicated by the lack of human data, use of varying formulations of toxin by different investigators, changes in manufacturing processes, and factual errors in the published literature.²⁶ Arnon and coauthors estimated that “lethal amounts of crystalline type A toxin for a 70-kg human would be approximately 0.09 to 0.15 µg intravenously or intramuscularly, 0.70 to 0.90 µg inhalationally, and 07 µg orally,”¹¹ but it is unclear whether these values can be applied reliably to any currently available commercial product.

In a large series of 139 patients with cervical dystonia randomized to treatment with BoNT type A or BoNT type B, no difference in efficacy was found between serotypes; the groups were also equivalent in frequency of adverse effects such as neck pain and neck weakness, but dry mouth and dysphagia were more common in the group treated with BoNT type B.⁴⁷

Following repeated injections of therapeutic doses of BoNT, patients may develop neutralizing antibodies that subsequently may limit the efficacy of the toxins; this situation should prompt a clinician to switch to use of a different toxin type.²⁶ In Japan and the United Kingdom, a preparation of BoNT type F is available for use when antibodies to type A develop.¹²² Some studies suggest that animals receiving BoNT type F have more transient and reversible weakness than that associated with types A and B.²³ In 1998, the formulation of Botox was changed to reduce the amount of potentially antigenic protein (from 25 ng of neurotoxin complex protein per 100 units to 5 ng of complex protein per 100 units), and studies in patients with cervical dystonia demonstrate a sixfold lower rate of development of anti-BoNT antibodies with the newer formulation.^{67a} For Xeomin the protein content is 0.6 ng per 100 units, while Dysport contains 4.35 ng of protein per 500 unit-vial (ie, 0.87 ng per 100 units).

Although one early marketing assumption was that the neurotoxin does not diffuse from the injection site, BoNT does diffuse into adjacent tissues and produce local adverse effects.¹⁰⁸ Systemic manifestations are of concern when an inadvertent, excessive, or misdirected dose of toxin is administered, or in the setting of a neuromuscular disorder that may be previously undiagnosed, as in one case in which injection of BoNT type A unmasked Lambert-Eaton myasthenic syndrome (LEMS).⁵⁰ In addition, a number of studies demonstrate that even appropriately injected doses result in neuromuscular junction abnormalities throughout the body, occasionally producing autonomic dysfunction without muscle weakness.^{56,73,96} Several cases of iatrogenic botulismlike symptoms, including diplopia and severe generalized muscle weakness with widespread electromyographic abnormalities, have resulted from therapeutic doses of intramuscular BoNT injections.^{17,21,140} A 2008 report raised the possibility that BoNT type A may undergo retrograde axonal transport and transcytosis to afferent neurons,⁵ suggesting a potential mechanism for such generalized effects. However, the reproducibility and clinical significance of these findings have yet to be established.

In a well publicized case in late 2004, four patients in Florida developed paralysis after being injected with BoNT type A. An FDA investigation revealed that these patients were injected by an unlicensed physician who obtained raw toxin (not approved for medical purposes) and administered it at a dose 2000 to 100,000 times greater than that used in clinical practice.³ These events were not believed to be relevant to the use of approved pharmaceutical BoNT. In February 2008, the FDA issued an Early Communication stating that it was reviewing safety data on BoNT after receiving reports of hospitalization or death in patients injected with these agents, mostly in children treated for cerebral palsy–associated spasticity.¹⁴² In 2009, the FDA mandated changes to the prescribing information for the BoNT products, requiring a Boxed Warning highlighting the possibility of potentially life-threatening effects distant from the injection site; a Risk Evaluation and Mitigation Strategy, including a Medication Guide to help patients understand the risks and benefits of the botulinum toxins; and changes of the drug names to reinforce differences between the potencies of the individual products and the lack of interchangeability among them.¹⁴³

Inhalational Botulism

Inhaled BoNT is estimated to be 100 times more potent than orally ingested BoNT; a single gram of toxin, if disseminated evenly, could kill more than 1 million people.¹¹ A 1962 report from West Germany described three veterinary workers

who inhaled BoNT type A from the fur of animals they were handling; on the third day after exposure they developed mucus in the throat, dysphagia, and dizziness, and on the next day they developed ophthalmoparesis, mydriasis, dysarthria, gait dysfunction, and weakness.¹¹ Use of aerosolized BoNT as a bioweapon has been attempted by terrorists in Japan, and Iraq has developed BoNT (along with anthrax and aflatoxin) as part of a biological warfare program^{11,153} (Chap. 133).

Diagnostic Testing

The CDC case definition for food-borne botulism is established in a patient with a neurologic disorder manifested by diplopia, blurred vision, bulbar weakness, or symmetric paralysis in whom³⁵

- BoNT is detected in serum, stool, or implicated food samples; or
- *C. botulinum* is isolated from stool; or
- A clinically compatible case is epidemiologically linked to a laboratory-confirmed case of botulism.

Routine laboratory studies, including cerebrospinal fluid analysis, are normal in patients with botulism but are generally performed to exclude other etiologies. Specific tests that can be helpful in diagnosing botulism are discussed below.

Edrophonium Testing

Edrophonium (Tensilon) is a rapidly acting and short-acting cholinesterase inhibitor that can be useful in the diagnosis of myasthenia gravis. It is occasionally used to differentiate myasthenia gravis from botulism. This drug inhibits the metabolism of acetylcholine located in synapses, permitting continued binding with the reduced number of postsynaptic acetylcholine receptors in myasthenia gravis.

A syringe containing 10 mg of edrophonium is prepared, and then a test dose of 1 to 2 mg is administered intravenously. A positive result (ie, consistent with myasthenia gravis) consists of dramatic improvement in the strength of weak muscles within 30 to 60 seconds, lasting 3 to 5 minutes. If there is no effect, the remainder of the edrophonium is given and the same effect sought. Ideally, a second syringe is filled with saline and the test performed under double-blind conditions to ensure accurate assessment and remove the potential of a placebo effect.

Because release of acetylcholine is impaired in botulism, preventing its catabolism with anticholinesterase drugs typically has little clinical benefit, but an effect may be observed if some neurons maintain the ability to release acetylcholine. Thus, in rare cases, early in the course of botulism injection of edrophonium results in limited improvement in strength that is far less dramatic than occurs in patients with myasthenia gravis.¹⁰²

Electrophysiologic Testing

In all forms of botulism, sensory nerve action potentials are normal. Motor potentials are typically reduced in amplitude (although this reduction may not be appreciated unless severely affected muscles are studied), but conduction velocity is not affected. Repetitive nerve stimulation at high frequencies would be expected to result in an increment of the amplitude of the motor potential, given the presynaptic localization of the defect, but this finding is neither sensitive nor specific; it also may be more common in disease due to BoNT type B than with type A.^{44,82} A marked incremental response with high frequency repetitive stimulation is more likely to suggest LEMS than botulism. Likewise, a decremental response to low-frequency repetitive nerve stimulation is characteristic of LEMS but is not consistently present in botulism.⁸²

The needle electromyography (EMG) examination in botulism is characterized by low-amplitude, short-duration motor unit action potentials (MUAPs), due to blockade of neuromuscular transmission in many muscle fibers (Fig. 41–2). Polyphasic MUAPs are also common. Recruitment is usually normal but may be reduced in severely affected muscles if all muscle fibers of a motor unit are blocked. Spontaneous activity, including positive sharp waves and fibrillation potentials, is often seen.

FIGURE 41–2. Schematic representations of repetitive nerve stimulation at low (5/sec) and high (50/sec) frequencies. In

botulism (**A**), repetitive stimulation produces a small-muscle action potential that facilitates (increases in amplitude) at higher frequencies. This effect (which, although classic, is not found in all cases of botulism) results from increased acetylcholine release with high-frequency stimulation because of intracellular calcium accumulation. In contrast, myasthenia gravis (**B**) is associated with a normal muscle action potential amplitude and a decremental response at low-frequency stimulation with a normal response at high-frequency stimulation. Myasthenia gravis, a disorder of the muscle end plate, produces this decremental response at low frequencies because the natural reduction in acetylcholine response with subsequent stimulation falls below threshold.^{105,148}

Although these electrodiagnostic abnormalities can support the diagnosis of botulism, they can be subtle. Nerve conduction studies and EMG are most useful in their ability to exclude differential diagnostic considerations, including Guillain-Barré syndrome and other neuropathies (both demyelinating and axonal), poliomyelitis, and myasthenia gravis. Moreover, there are no pathognomonic electrophysiologic findings in botulism; in particular, the findings can closely resemble those of a myopathic process, and muscle biopsy may be necessary to exclude such a condition.⁸²

Laboratory Testing

Samples of serum, stool, vomitus, gastric contents, and suspected foods should be subjected to anaerobic culture (for *C. botulinum*) and mouse bioassay (for BoNT) (Table 41–3). A list of the patient’s medications should accompany each sample to exclude other xenobiotics that might interfere with the assay (eg, pyridostigmine) or be toxic to the mice. The serum samples must be collected prior to initiation of antitoxin therapy. If wound botulism is suspected, serum, stool, exudate, débrided tissue, and swab samples should be collected. For infant botulism, feces and serum samples also should be obtained. Infants who are constipated may require an enema with nonbacteriostatic sterile water to facilitate collection. All enema fluid and stool should be sent for analysis. The specimens should be refrigerated (not frozen) and examined as soon as possible after collection. Detailed information on specimen collection and examination is available online from the CDC (<http://www.cdc.gov/ncidod/dbmd/diseaseinfo/files/botulism.pdf>).³⁴

TABLE 41–3. Epidemiologic and Laboratory Assessment of Botulism^a

Classification	Food Borne	Infant	Wound	Adult Intestinal Colonization
Toxin type	A, B, E, F, G in humans; C, D in animals	A, B, C, F	A, B	A
Route	Ingestion of toxin	Ingestion of bacteria and spores	Wound, abscess (sinusitis)	Ingestion of bacteria and spores
Specimens	Stool: positive for bacteria/spores and toxin	Stool: positive for bacteria/spores and toxin for up to 8 weeks after recovery	Wound site: Gram stain, aerobic and anaerobic cultures; positive for bacteria/spores	Stool: positive for bacteria/spores and toxin
Botulinum toxin in serum	Yes	Yes	Yes	Yes
Bacteria/spores in food	Yes	Yes	No	Yes
Botulinum toxin in food	Yes	No	No	No

^a“Toxin” refers to botulinum toxin. “Bacteria/spores” refers to *C. botulinum*.

In the mouse lethality assay, the standard test for detecting BoNT, the sample (serum, stool, or food) is injected intraperitoneally into mice, which are then observed for development of signs of botulism. Control mice are injected with the sample as well as antitoxin. This test is very sensitive, with a detection limit of 0.01 ng/mL of sample eluate. However, it is laborious, expensive, and a positive result may not appear for several days, reducing its usefulness in early diagnosis of botulism.⁷⁵ Alternative methods for detecting BoNT, including immunological methods (eg, enzyme-linked immunosorbent assay {ELISA}) and endopeptidase assays, are being explored.

C. botulinum can be cultured under strict anaerobic conditions. Stool specimens are incubated anaerobically and then subcultured on egg yolk agar to assess for lipase production, although this test is not specific as other clostridia also produce lipase. Numerous protocols using polymerase chain reaction and probe hybridization to detect and identify *C. botulinum* are described but these have not yet been applied widely in clinical practice.⁷⁵

MANAGEMENT

Supportive Care

Respiratory compromise is the usual cause of death from botulism. To prevent or treat this complication, hospital

admission of the patient and of all individuals with suspected exposure is mandatory. Careful continuous monitoring of respiratory status using parameters such as vital capacity, peak expiratory flow rate, negative inspiratory force (NIF), pulse oximetry, end-tidal CO₂, and the presence or absence of a gag reflex is essential to determine the need for intubation or tracheostomy, as the patient begins to manifest signs of bulbar paralysis.¹¹⁶ The most reliable, readily obtainable test is the NIF, which can be used in most institutions to determine the need for intubation. When suspicion of disease is high, and the vital capacity is less than 30% of predicted or the NIF is less than −30 cm H₂O, intubation should be strongly considered.^{86,135}

Reverse Trendelenburg positioning at 20° to 25° with cervical support has been suggested to be beneficial by enhancing diaphragmatic function, but the clinical application to seriously ill patients has not been validated.¹¹ This approach may reduce the risk of aspiration while decreasing the pressure of abdominal viscera on the diaphragm, with resultant improvement in ventilatory effort.

In addition to attention to respiratory issues, patients require nutrition (enteral or parenteral) and prompt recognition and treatment of secondary infections.

Gastric Decontamination

An attempt should be made to remove the spores and toxin from the gut. Although most patients present after a substantial time delay, the bacteria and/or BoNT may still be present hours or even days later. Activated charcoal should be a routine part of supportive care, because in vitro it adsorbs BoNT type A and probably also the other BoNT types.⁵⁷ Gastric lavage or emesis should be initiated only for an asymptomatic person who has very recently ingested a known contaminated food. If a cathartic is chosen, sorbitol is preferable because other cathartics such as magnesium salts may exacerbate neuromuscular blockade. Theoretically, whole-bowel irrigation may have a role in decontamination, particularly if there is concern about initiating emesis, but interventions other than activated charcoal have not been evaluated under these circumstances.

Wound Care

Thorough wound débridement is the most critical aspect in the management of wound botulism and should be performed promptly.^{66,76} Antibiotic therapy alone is inadequate, as evidenced by several case reports of disease despite antibiotic therapy. Penicillin G is one of many drugs with excellent in vitro antimicrobial efficacy against *C. botulinum* and is useful for wound management.¹³⁴ However, neither does penicillin play a role in the management of botulism caused by preformed toxin nor does it prevent gut spores from germinating. For these reasons, penicillin is not considered useful in infant and adult infectious botulism, and it is not by itself considered adequate for wound botulism. Medications that may interfere with neuromuscular transmission, such as aminoglycoside antibiotics¹¹³ and clindamycin,¹¹⁸ should not be used.

Guanidine, Dalfampridine (4-Aminopyridine), and 3,4-Diaminopyridine

Guanidine is no longer recommended for treatment of botulism, because its merits were not substantiated.^{52,69} (See previous editions of this text for a more extensive discussion.) Several studies¹¹¹ and case reports⁴⁸ have proposed that dalfampridine (4-aminopyridine) and 3,4-diaminopyridine are effective in improving neuromuscular transmission by enhancing acetylcholine release from the motor nerve terminal.¹¹¹ Dalfampridine (Ampyra) is FDA-approved to improve walking in patients with multiple sclerosis, but its potential to induce seizures at therapeutic doses limits its clinical usefulness. In a rat BoNT type A model of botulism, 3,4-diaminopyridine restored neuromuscular function and enhanced animal survival.¹²⁴ The therapeutic efforts for those with LEMS and the successful animal results all suggest that further investigative efforts are necessary. The fact that 3,4-diaminopyridine does not substantially cross the blood–brain barrier, resulting in limited CNS manifestations, makes this xenobiotic appropriate for further investigation.

Botulinum Antitoxin

Since the 1960s, passive immunization with antitoxin has been used to neutralize unbound BoNT. In the United States, the CDC supplies equine-derived antitoxin through state and local (except in California and Alaska) health departments. It is indicated for patients with food-borne or wound botulism. In 2010, an investigational heptavalent botulinum antitoxin (H-BAT) replaced the previously available bivalent antitoxin against BoNT types A and B and investigational antitoxin against type E. It contains equine-derived antibody to the seven known botulinum toxin types (A through G) and currently is the only botulinum antitoxin available in the United States for naturally occurring noninfant botulism.⁴¹ In a review of 132 cases of type A food-borne botulism, a lower fatality rate and a shorter course of illness were demonstrated for patients who received trivalent antitoxin, even after controlling for age and incubation period.¹³⁵ The earlier a patient received antitoxin, the shorter was the clinical course. In addition, no respiratory arrests occurred more than 5 hours after antitoxin was administered. Two studies on the use of antitoxin in the presence of wound botulism demonstrated that the longer the

delay to antitoxin administration, the more prolonged the requirement for ventilatory support and the poorer the outcome.⁴³ Consequently, antitoxin should be requested from the CDC at the time the diagnosis of botulism is first suspected.

Serum, stool, and gastric aspirate samples should be collected prior to administration of antitoxin. Because H-BAT is an investigational drug, informed consent must be obtained before giving it. The entire vial of antitoxin should be given intravenously as a 1:10 vol/vol dilution in 0.9% sodium chloride at rate of 0.5 mL/min for 30 minutes, optionally increasing to 1 mL/min for 30 minutes and then 2 mL/min if tolerated. Premedication with corticosteroids and antihistamines is recommended in children and in patients with a suspected history of reaction to equine-derived products. Although hypersensitivity skin testing for horse serum traditionally has been recommended prior to treatment with equine based antitoxins, it is not required for H-BAT; because H-BAT is despeciated, the risk of reaction may be lower than with previous products. Epinephrine and diphenhydramine should be readily available to treat anaphylaxis or hypersensitivity reactions.⁴¹ The overall rate of adverse reactions, including hypersensitivity and serum sickness,²⁴ to equine-derived botulinum antitoxins is reported as 9% to 17%, with an incidence of anaphylaxis as high as 1.9%.^{16,88} However, the risk is likely to be lower with the despeciated product.

The antitoxin neutralizes only unbound toxin, and consequently it can prevent paralysis but does not affect already paralyzed muscles.⁵⁴ Due to the high mortality rate associated with food-borne botulism, the antitoxin should be given to patients in whom the diagnosis is suspected; treatment should not be delayed while awaiting laboratory confirmation of the diagnosis. In the event of a potential outbreak of food-borne botulism, asymptomatic individuals should be closely monitored for early signs of illness so that antitoxin can be administered promptly¹²¹ (Antidotes in Depth: A6).

Treatment of Infant Botulism

Like adults, infants with botulism require intensive care, with meticulous monitoring for respiratory compromise. Autonomic dysfunction may also occur. Constipation may be severe.

Equine-derived antitoxin is not recommended in infant botulism because of doubtful efficacy as well as safety concerns.^{34,68,74,115} In October 2003, the FDA licensed human-derived botulism antitoxin antibodies as botulism immune globulin (BabyBIG) for treatment of infant botulism types A and B.⁷ A randomized trial of 122 cases of infant botulism showed that treatment with intravenous botulism immune globulin significantly reduced the length of hospital stay and intensive care, duration of mechanical ventilation and tube or intravenous feeding, and cost of hospitalization relative to placebo, without causing serious adverse effects.^{12,53} Similar results were seen in a 2007 retrospective chart review.¹⁴¹ BabyBIG is available from the California Department of Health Services Infant Botulism Treatment and Prevention Program (<http://www.infantbotulism.org>).²⁹

Prevention

Measures used to prevent infant botulism include limiting exposure to spores by thoroughly washing foods and objects that might be placed in a child's mouth. In addition, honey should not be given to infants younger than 6 months.

Numerous vaccination strategies are under investigation, including several recombinant vaccines that have shown promise in protecting against botulism in animal and human trials.^{18,127}

PROGNOSIS

The prolonged and variable period of recovery that occurs after exposure to BoNT is directly related to the extent of neuromuscular blockade and neurogenic atrophy as well as the regeneration rates of nerve endings and presynaptic membranes.⁸³ If the patient has excellent respiratory support during the acute phase and receives adequate parenteral nutrition, residual neurologic disability may not occur. Although the initial course may be protracted, near-total functional recovery can follow within several months to one year. Common long-term sequelae include dysgeusia, dry mouth, constipation, dyspepsia, arthralgia, exertional dyspnea, tachycardia, and easy fatigability.

The status of 13 patients who survived a toxin type B botulinum outbreak was characterized 2 years later by persistent dyspnea and fatigue, although surprisingly, pulmonary function tests had returned to normal in all patients.¹⁴⁸ Inspiratory muscle weakness persisted in 4 of 13 patients. Maximal oxygen consumption and maximal workload during exercise were diminished in all patients, and all had more rapid shallow breathing and a higher dyspnea score than controls. The reasons for premature exercise termination may be multifactorial. Although persistent respiratory muscle weakness may be an explanation, most dyspnea and fatigue appeared to be related to reduced cardiovascular fitness, leg fatigue, and diminished nutrition.¹⁴⁹

A 2007 case-control series reported long-term outcomes in 217 adults with food-borne botulism in the Republic of Georgia. Six patients died; the remaining 211 were interviewed a median of 4.3 years after onset of disease. They were significantly more likely than control subjects to report ongoing fatigue, dizziness, weakness, dry mouth, difficulty lifting

things, and difficulty breathing with moderate exertion.⁵⁸

PREGNANCY

At least three cases of botulism occurring during pregnancy are reported. One case occurred during the second trimester¹⁰⁶ and two cases occurred during the third trimester.¹³¹ Although in two cases BoNT or *C. botulinum* was isolated from the mother prior to administration of antitoxin therapy, no detectable toxin was isolated from the neonates in either of the third-trimester cases. The large molecular weight of the neurotoxin (150 kDa) makes passive diffusion through the placenta unlikely,⁶⁴ and, although theoretically possible, no active transport system has been identified.¹³¹ None of the three neonates had neurologic evidence of botulism. Appropriate care of the mother and preparation for maternal complications of delivery appear to ensure the best potential outcome for the infant.

A 2006 survey of physicians identified 16 women who were treated with BoNT type A during 19 pregnancies. One patient was injected while carrying twins, and another was treated during three separate singleton pregnancies. One patient who received a single session of 300 units of BoNT for cervical dystonia miscarried; she had a history of previous miscarriages. Another patient underwent a therapeutic abortion. No other complications occurred. Nevertheless, the authors “do not recommend injection of pregnant women ... until more data are available.”⁹⁰ All commercially available BoNT products are FDA pregnancy category C. It is unknown whether BoNT is excreted in breast milk.

EPIDEMIOLOGIC AND THERAPEUTIC ASSISTANCE

Whenever botulism is suspected or proven, the local health department should be contacted. The health department should report to the CDC Emergency Operations Center at 770-488-7100. The CDC can provide or facilitate diagnostic, consultative, and laboratory testing services, access to botulinum antitoxin, and assistance in epidemiologic investigations. All foods that are potentially responsible for the illness should be refrigerated and preserved for epidemiologic investigation. The merits of this surveillance and antitoxin release system were demonstrated in Argentina,¹⁴⁵ where the CDC assisted in establishing nation-specific principles, including local stocking of antitoxin and establishing mechanisms for distribution, emergency identification, response, and laboratory confirmation of suspected cases. Expansion of this system to other nations will enhance worldwide botulism surveillance for food-borne botulism and for potential terrorist dissemination of BoNT.¹²⁰

SUMMARY

- Most cases of botulism in the United States affect infants younger than 6 months of age. Because of an epidemiologic association, honey should not be given to babies younger than one year of age.
- Most cases of food-borne botulism relate to food processed at home under improper conditions.
- The diagnosis of botulism should be considered in patients presenting with diplopia, blurred vision, bulbar weakness, and/or symmetric paralysis.
- BabyBIG, a botulism immune globulin, is available for treatment of infant botulism types A and B, and there is a heptavalent botulinum antitoxin against serotypes A through G for noninfants. Treatment should not be delayed while laboratory diagnosis is pending.
- Botulinum toxins are injected therapeutically (both on-label and off-label) for numerous conditions, and they are safe and effective when used properly.

A6 ANTIDOTES IN DEPTH

Botulinum Antitoxin

Silas W. Smith and Howard L. Geyer

INTRODUCTION

Antidotal therapies for adult and infant *Clostridium botulinum* infection are available as equine and human derived immunoglobulin antitoxins. Antitoxins may be beneficial for most clinical forms of botulism, although their utility is restricted to limiting disease progression rather than to reversing clinical manifestations.

HISTORY

Beginning in the 1930s, a formalin-inactivated toxoid against botulinum neurotoxin was first tested in humans, and in 1946 a bivalent (AB) formaldehyde-inactivated toxoid was deployed by the US Department of Defense as prophylaxis for at-risk individuals during the US Offensive Biological Warfare Program.^{48,56} By 1999, an equine trivalent antitoxin (ABE) was available to treat botulism.¹³ From 1999 to 2010, equine-derived, licensed bivalent botulinum antitoxin AB (BAT-AB) and investigational monovalent serotype E botulinum antitoxin (BAT-E) were available in the United States as immunoglobulin preparations. BAT-AB was used for patients with presumed wound botulism, and BAT-AB and BAT-E antitoxins were coadministered to patients with food-borne botulism. On March 13, 2010, equine heptavalent botulinum antitoxin (H-BAT, NP-018), the investigational new drug sponsored by the Centers for Disease Control and Prevention (CDC), replaced licensed bivalent BAT-AB and investigational botulinum antitoxin E.² Effective November 30, 2011, the CDC also stopped providing the investigational pentavalent (ABCDE) botulinum toxoid (PBT) for vaccination of workers at risk for occupational exposure.³ BabyBig, or Botulism Immune Globulin Intravenous (Human) (BIG-IV), was created by the California Department of Health Services (CDHS) in 1991 to treat infants afflicted by type A or type B botulism; it received Food and Drug Administration (FDA) approval in 2003.^{4,22} On March 22, 2013, the FDA approved H-BAT, equine Botulism Antitoxin Heptavalent (A, B, C, D, E, F, G) which is currently available.

PHARMACOLOGY

Chemistry/Preparation

A toxoid refers to an inactivated form of a bacterial toxin. An antitoxin is an antibody or antibody fragment capable of neutralizing a toxin. Multiple injections over months of formalin-inactivated toxoid are required to effectively immunize horses against botulinum toxin and to produce equine-derived antitoxins.³¹ The resultant antibotulinum immunoglobulin requires several purification and preparation steps.²⁵ H-BAT is produced by pooling plasma from horses immunized with specific botulinum toxoid subtypes (A–G), followed by pepsin digestion and blending of the seven serotype antitoxins into a heptavalent product.¹² H-BAT contains anti-type A, 4500 international units (IU); anti-type B, 3300 IU; anti-type C, 3000 IU; anti-type D, 600 IU; anti-type E, 5100 IU; anti-type F, 3000 IU; and anti-type G, 600 IU.²⁹ As the equine H-BAT is “despeciated” by pepsin enzymatic cleavage and removal of the Fc fragment portion, the result is a product composed of $\geq 90\%$ Fab and F(ab')₂ immunoglobulin fragments and less than 2% intact immunoglobulin G (IgG).² This decreases the risk of immediate hypersensitivity reactions and serum sickness.

Human whole IgG BIG-IV is derived from cold ethanol precipitation of pooled adult plasma collected from human donors immunized multiple times with PBT (A–E).^{37,52} The reconstituted product (50 ± 10 mg immunoglobulin/mL) contains greater than or equal to 15 IU/mL anti-type A toxin activity and greater than or equal to 4 IU/mL anti-type B toxin activity; antibody titers against botulinum neurotoxins C, D, and E remain undetermined.^{22,29}

Mechanism of Action

Current antitoxins (whether equine or human derived) bind to and neutralize free botulinum toxin.¹³ Thus, antitoxins are

ineffective against toxin bound to presynaptic acetylcholine release sites, toxin endocytosed by peripheral neuronal cells, and intracellular botulinum toxin light chain endopeptidase activity.¹⁰ Affected presynaptic end plates must regenerate in order to regain function.

Pharmacokinetics and Pharmacodynamics

Antidotal antibody fragments (eg, $F(ab')_2$, $F(ab')$, and single-chain variable fragments {scFv}) demonstrate shorter half-lives compared to whole immunoglobulins.³² Improved renal clearance and uptake by vascular endothelium and surrounding tissues may contribute to this effect.⁴² While linking fragments to polyethylene glycol can extend their half-life,¹⁶ this methodology remains investigational. Compared to the half-lives for antitoxin types A, B, and E of 6.5, 7.6, and 5.3 days measured in a patient provided whole immunoglobulin trivalent antitoxin, clinical trials following single vial administration determined shorter H-BAT antitoxin half-lives of anti-A (8.64 hours), anti-B (34.20 hours), anti-C (29.60 hours), anti-D (7.51 hours), anti-E (7.75 hours), anti-F (14.10 hours), and anti-G (11.70 hours).¹¹ These half-lives increased to 10.20 hours, 57.10 hours, 45.60 hours, 7.77 hours, 7.32 hours, 18.20 hours, and 14.70 hours, respectively, when two vials were administered.^{11,20,24} The volume of distribution ranges from 1465 mL (anti-D) to 14,172 mL (anti-E), depending on the number of vials.¹¹ The more rapid clearance of Fab and $F(ab')_2$ fragments compared to whole IgG may necessitate repeat H-BAT dosing in patients with wound or intestinal colonization or other cases in which in situ botulinum toxin production continues after antitoxin clearance.² Indeed, recurrence of paralysis was reported following H-BAT therapy in a patient with persistent type F intestinal colonization.²⁰

By convention, one IU of botulinum antitoxin neutralizes 10,000 mouse intraperitoneal median lethal doses (MIPLD₅₀) of toxin types A, B, C, D, and F, or 1000 MIPLD₅₀ of toxin type E (the IU for type G remains undefined).¹⁴ Thus, for example, in the doses found in H-BAT, the 4500 IU of anti-A, 3300 IU of anti-B, 3000 IU of anti-C, 600 IU of anti-D, 5100 IU of anti-E, and 3300 IU of anti-F would offset a total of 4.5×10^7 MIPLD₅₀ of botulinum A toxin, 3.3×10^7 MIPLD₅₀ of botulinum B toxin, 3.0×10^7 MIPLD₅₀ of botulinum C toxin, 6.0×10^6 MIPLD₅₀ of botulinum D toxin, 5.1×10^6 MIPLD₅₀ of botulinum E toxin, and 3.0×10^7 MIPLD₅₀ of botulinum F toxin, respectively.⁴⁶ These values would be anticipated to provide significant neutralization; patient serum botulinum toxin concentrations in food-borne botulism are usually less than 10 MIPLD₅₀/mL and rarely exceed 32 MIPLD₅₀/mL, using a plasma volume of 3000 mL reported previously.^{5,24,45} In isolated outbreaks, botulinum toxin concentrations in adult serum samples collected less than 18 hours after exposure are reported to be as high as 160 MIPLD₅₀/mL.⁷ Other recent cases have also yielded human serum botulinum toxin concentrations of type A of 1800 MIPLD₅₀/mL.⁴⁶ Following single vial administration, the reported H-BAT maximum concentration values¹² of 2.69 IU/mL for anti-A, 1.90 IU/mL for anti-B, 2.26 IU/mL for anti-C, 0.81 IU/mL for anti-D, 0.94 IU/mL for anti-E, and 2.37 IU/mL for anti-F would be anticipated to neutralize 2.69×10^4 MIPLD₅₀/mL of botulinum A toxin, 1.90×10^4 MIPLD₅₀/mL of botulinum B toxin, 2.26×10^4 MIPLD₅₀/mL of botulinum C toxin, 8.1×10^3 MIPLD₅₀/mL of botulinum D toxin, 9.4×10^2 MIPLD₅₀/mL of botulinum E toxin, and 2.37×10^4 MIPLD₅₀/mL of botulinum F toxin. One study that measured four patients' serum antitoxin concentrations following trivalent antitoxin (ABE) administration determined that those patients' measured antitoxin titers would retain the capability to neutralize 1500, 1000, and 12 times the anticipated toxin concentrations of types A, B, and E, respectively.²⁴ Complexity in anticipating or interpreting absolute neutralization efficacy is due to the fact that animal studies have revealed that the relationship between circulating neutralizing antibody concentrations and the amount of botulinum toxin neutralized is nonlinear, leading to a more efficacious, disproportional increase in botulinum toxin neutralization as antibody concentration is increased.⁴⁵

The half-life of BIG-IV is approximately 28 days.²⁹ BIG-IV anti-A titers were 0.5371 ± 0.2134 IU/mL on day one. Since one IU neutralizes 10,000 mouse intraperitoneal median lethal doses (MIPLD₅₀) of botulinum toxin A, this yields approximately titers of 5370 MIPLD₅₀/mL.^{14,29} Thus, a single infusion is anticipated to neutralize all botulinum toxin that might be absorbed from an infant's colon for several months.⁶

Related Agents

In order to properly interpret earlier botulism studies, it is important to recall that the previously available, equine BAT-AB antitoxin contained 7500 IU of anti-A antitoxin and 5500 IU of anti-B antitoxin.⁴¹ BAT-E contained 5000 IU of antitoxin. Trivalent antitoxin (ABE) contained 7500 IU of anti-A, 5500 IU of anti-B, and 8500 IU of anti-E antitoxins.²⁷ Investigational, whole, and fragment-derived monoclonal antibodies that have been raised in murine and equine species against types A and B are also being explored.^{31,32}

Investigational PBT vaccine, combining individual monovalent toxoids, was initially manufactured by Parke Davis more than 50 years ago and was subsequently produced by the Michigan Department of Public Health under contract from

the US Army.^{21,47} A replacement vaccine developed by US Army Medical Research Institute for Infectious Diseases (USAMRIID)—recombinant botulinum vaccine (rBV A/B)—is designed to protect adults 18 to 55 years of age against botulism type A (subtype A1) and type B (subtype B1).²³ It has been studied in animals and, completed human clinical trials await publication, although approval may be pursued under the FDA Animal Rule.^{17,23,44} Other recombinant subunit vaccines against C₁, D, E, and F have demonstrated efficacy in animals.⁴⁷ Humanized monoclonal antibodies, small peptides and peptide mimetics, receptor mimics, and small molecules targeting the endopeptidase activity are other avenues being explored for botulism treatment.¹⁰

ANTITOXIN ROLE IN ADULT BOTULISM

Rigorous adult morbidity and mortality studies are difficult to perform due to botulism's rarity, varied exposure and presentation, delayed recognition when bound toxin is no longer removable by antitoxin, and inconsistent clinical care. Given the delay involved in confirmatory testing by the CDC or public health laboratories and the lack of antitoxin reversal potential, the decision to administer H-BAT will often be made on the basis of empirical clinical and epidemiological grounds. Earlier disease recognition and an organized public health approach comprising surveillance, emergency notification, stocking, a release and distribution system, and laboratory confirmation appear to be responsible for decreasing morbidity and increasing survival after typical food-borne botulism.^{43,55} Simian experiments demonstrate reduced mortality with antitoxin administration.³⁵ Early antitoxin administration is a critical factor affecting clinical course and outcome. In a 1963 type E outbreak, all three patients who died failed to receive antitoxin, whereas three of five who received botulinum antitoxin survived.³⁰ Trivalent equine antitoxin decreased the fatality rate of botulinum A poisoning in a case series from 1973 to 1980.⁵¹ Patients who received antitoxin within the first 24 hours after symptom onset had a shorter disease course, although their mortality rate was equivalent to those who received antitoxin later. Age over 60 years and being an index patient conferred a greater mortality risk; a shorter incubation period of less than 36 hours (a surrogate measure of toxin dose) increased duration of hospitalization, mechanical ventilation, and time to sustained improvement.⁵¹ The case-fatality rate was 3.5% in patients with type E botulism who were provided antitoxin and 28.9% for untreated control subjects from previous years, although the utilization of supportive measures was uncontrolled.²⁸ In a retrospective review of 29 patients admitted from 1991 to 2005 with type A and a single case of type B wound botulism, a delay in antitoxin administration correlated with increased length of intensive care unit (ICU) stay.³⁶ In 20 patients with type A wound botulism treated from 1991 to 1998, those who received antitoxin within 12 hours of presentation required mechanical ventilation 57% of the time for a median duration of 11 days, compared to those who failed to receive antitoxin within 12 hours in whom 85% require mechanical ventilation for a median duration of 54 days.⁴⁰ Again, a shorter time to presentation heralded more severe disease (respiratory failure). A third wound botulism series (types A and B) with seven patients confirmed the importance of early therapy; those receiving antitoxin more than 8 days from symptom onset fared poorly compared to those receiving it within 4 days of symptom onset.¹⁵ Botulinum antitoxins are also beneficial in cases of iatrogenic botulism.⁴⁹ An earlier despeciated heptavalent botulism immune globulin (dBIG), which was prepared by the University of Minnesota under US Army contract, was deployed in the 1991 Egyptian type E botulism outbreak.²⁵ In a 2006 Thailand type A outbreak, heptavalent antitoxin was administered to 20 patients 5 days after toxin ingestion when respiratory failure was already present. Mechanical ventilation and hospital duration were shorter when compared to a historical study, and there were no deaths in those receiving antitoxin.⁵⁸

The absolute time frame for efficacy remains undetermined. In 109 patients treated under the CDC open-label protocol, H-BAT administration within 2 days after symptom onset (compared to >2 days) was associated with clinically significant, shorter mean durations of hospitalization (12.4 versus 26.1 days), ICU utilization (9.2 versus 15.8 days), and mechanical ventilation (11.6 versus 23.4 days).¹¹ However, circulating toxin can persist for long periods in patients with food-borne botulism. One study reported toxin detection in almost 20% of serum specimens taken greater than or equal to 10 days after toxin ingestion.⁵⁹ Furthermore, persistent, viable organisms or spores were present in stools 40% of the time at 10 days or more after toxin ingestion. A review of laboratory-confirmed botulism cases in Alaska from 1959 to 2007 demonstrated that toxin could be recovered in patients' sera up to 11 days after ingestion, while no serum specimens collected after antitoxin administration tested positive.¹⁹ In one case, toxin was detected in serum 12 days after the onset of descending paralysis.¹ Another patient in that multinational food-borne outbreak had toxin detected at 25 days after symptom onset.⁴⁶ Other isolated cases detail detectable circulating toxin as late as three and a half weeks after contaminated food consumption.¹⁸ Botulinum toxin-associated ileus might result in prolonged toxin exposure and continued absorption.

Collectively, these factors suggest that H-BAT might still prove clinically useful in patients with delayed presentations or disease recognition, in whom circulating toxins might present a persistent risk. Indeed, one report documented improvement when H-BAT was administered 48 hours after admission and many days after consumption of type-unspecified, botulism-contaminated canned corn.²⁶

A recently discovered, novel, eighth botulinum neurotoxin type H, recovered from an infant botulism patient, cannot be

neutralized by any of the currently available antitoxin therapies.^{7a,18a} Botulism poisoning does not appear to induce protective immunity or decrease subsequent morbidity or mortality associated with subsequent exposure in food or wound botulism.^{8,13,60} Thus, retreatment with antitoxin is required upon reexposure or in recurrent cases.

ANTITOXIN ROLE IN INFANT BOTULISM

BIG-IV is approved for treatment of patients younger than one year of age with infant botulism caused by toxin type A or B. BIG-IV does not treat rare serotype F disease, as human donors were vaccinated with PBT (A–E). In a double-blind and subsequent open-label trial, treatment with BIG-IV significantly reduced the overall length of hospital and ICU stay, the duration of mechanical ventilation, tube and intravenous feeding, and the cost of hospitalization.^{4,6} A retrospective review of 67 ICU patients with type A or B botulinum toxin from 1976 to 2005 found clinically significant decreases in length of hospital stay, ICU stay, and mechanical ventilation in patients who received BIG-IV versus those who did not.⁵³ Another retrospective review of patients with type A or B botulinum toxin from 1985 to 2005 reported a significant decrease in length of stay, a reduced need for nasogastric feeding, and duration of tracheal intubation in infants treated with botulism immune globulin.⁶⁰

BAT-AB and other equine derived products were rarely used in infants due to concern for anaphylaxis, life long hypersensitivity, and unclear efficacy.¹⁴ However, in situations where BIG-IV was unavailable due to lack of access or cost, BAT-AB treatment within 5 days of symptom onset significantly reduced overall hospital and ICU stays, duration of mechanical ventilation, tube feedings, and incidence of sepsis.⁵⁴

ADVERSE EFFECTS AND SAFETY ISSUES

Despite purification, inactivation, and filtration measures, potential transmission of blood-borne infectious agents from animal or human donors (pooled equine or human plasma) may still occur. Treatment with whole equine-derived antitoxins risks hypersensitivity reactions and serum sickness.⁴¹ Early rates of adverse reactions during the first decade during which botulinum antitoxin was available (1967–1977) ranged from 9% to 21%.^{9,34} The reported rates of anaphylaxis and serum sickness were 1.9% and 3.7%, respectively.⁹ However, the doses of antitoxin were larger than those subsequently used. H-BAT despeciation further decreases, but does not eliminate, this risk. Use of dBIG produced adverse reactions in 10 of 45 patients when used in one botulism type E outbreak.²⁵ These included nine “mild” reactions (local skin reactions, six; pruritus, one; urticaria, one; shivering, one) and one episode of “suggested serum sickness” without additional detail. The incidence of adverse effects of dBIG was similar to other internationally available antitoxins.²⁵ Healthy subjects administered H-BAT in clinical trials (56 total, of whom 20 received two vials) reported headache, pruritus, nausea, and urticaria at rates of 9%, 5%, 5%, and 5%, respectively.¹¹ Two moderate allergic reactions required treatment. Eleven subjects produced anti-BAT antibodies. The open-label CDC observation study revealed adverse reactions in 10% of 228 assessable patients; pyrexia, rash, chills, nausea, and edema occurred in 4%, 2%, 1%, 1%, and 1%, respectively.¹¹ There were no immediate hypersensitivity reactions, one cardiac arrest, and one episode of serum sickness. H-BAT contains maltose, which may interfere with certain non-glucose-specific blood glucose monitoring systems.

Hypersensitivity reactions might also occur to human BIG-IV, although this was not reported in clinical trials.²⁹ BIG-IV is contraindicated in patients with a prior history of severe reactions to other human immunoglobulin preparations and should be used cautiously in patients with or at risk for kidney dysfunction, because kidney dysfunction has been noted following treatment with other intravenous immunoglobulin products.²⁹ A mild, transient erythematous rash on the face or trunk was the most commonly reported adverse reaction. Potential but unreported adverse events include antibody development to immunoglobulin A (IgA) in patients with selective IgA deficiency and anaphylaxis upon subsequent exposure to blood products that contain IgA, aseptic meningitis syndrome, hemolytic anemia, thrombosis, transfusion-related acute lung injury, and hyperviscosity.²⁹ Administration of live virus vaccines (ie, measles, mumps, rubella, varicella) should be delayed for 5 months after infant BIG-IV treatment due to concerns of loss of immunization efficacy.

PREGNANCY AND LACTATION

Although there is limited information regarding H-BAT use in pregnancy, whole equine bivalent and trivalent antitoxins have been previously administered without apparent harm to the mother or the fetus.^{33,38,39,50} Pregnancy is not a contraindication to H-BAT. Given botulism’s life-threatening paralysis, treatment benefits would potentially exceed risks of harm, although all decisions are ultimately made on a case-by-case basis. H-BAT’s breast milk distribution is unknown. The labeled indication of BIG-IV for use in patients younger than one year of age does not address administration to pregnant women.²⁹

DOSING AND ADMINISTRATION

Close monitoring; medications including epinephrine, diphenhydramine, and corticosteroids, supportive airway modalities; and practitioners who are capable of diagnosing and treating anaphylactic or anaphylactoid reactions (including intubation competence) should be immediately available prior to and during antitoxin administration.

Botulism Antitoxin Heptavalent (A, B, C, D, E, F, G)

Unlike prior equine derived products, H-BAT does not require routine sensitivity testing prior to administration, although it may be considered for those at risk of acute hypersensitivity reactions. If required, skin sensitivity testing with H-BAT is performed by administering 0.02 milliliters of 1:1000 saline-diluted BAT intradermally on the volar surface of the forearm (enough to raise a small wheal) with concurrent positive (histamine) and negative (saline) control tests.¹¹ Read after 15 to 20 minutes, a positive test is a wheal with surrounding erythema at least 3 millimeters larger than the negative control test. The histamine control must be positive for valid interpretation. A negative test is followed with repeat testing using a 1:100 dilution and then careful administration if no reaction occurs.

Three separate dosing strategies are recommended for adults, pediatric patients (1–17 years), and infants younger than 1 year. The adult dose is one vial. The vial is diluted 1:10 in 0.9% sodium chloride and administered intravenously via an optional 15-micron in-line filter. Barring any infusion-related safety concerns, the initial rate is 0.5 mL/min for the first 30 minutes, which is increased to 1 mL/min for the next 30 minutes, and then to 2 mL/min until completion of the infusion. For pediatric patients, the dose is a percentage of adult (one vial) dose calculated according to the dosing rule summarized in the package insert. For pediatric patients with a body weight ≤ 30 kg, the percentage of the adult dose to administer equals twice the body weight (in kg); for patients with a body weight >30 kg, the percentage of the adult dose to administer equals the weight (in kg) + 30. This rule yields the recommended percentages of the adult dose to administer according to the following pediatric weight intervals: 10 to 14 kg, 20%; 15 to 19 kg, 30%; 20 to 24 kg, 40%; 25 to 29 kg, 50%; 30 to 34 kg, 60%; 35 to 39 kg, 65%; 40 to 44 kg, 70%; 45 to 49 kg, 75%; 50 to 54 kg, 80%; and greater than or equal to 55 kg, 100%.¹¹ Without ever exceeding the adult rates, the infusion is initiated at a rate of 0.01 mL/kg/min for the first 30 minutes, which is increased 0.01 mL/kg/min every 30 minutes, to a maximum infusion rate of 0.03 mL/kg/min until completion. Infants (<1 year) receive 10% of the adult dose regardless of body weight. The infusion is initiated at a rate of 0.01 mL/kg/min for the first 30 minutes, which is increased 0.01 mL/kg/min every 30 minutes, to a maximum infusion rate of 0.03 mL/kg/min until completion.

Big-IV

The lyophilized product is reconstituted with 2 mL of sterile water for injection, to obtain a 50 mg/mL BIG-IV solution. The vial should not be shaken; this causes foaming. Infusion should begin within 2 hours of reconstitution. A dedicated intravenous line using low-volume tubing and a constant infusion pump are used to provide 75 mg/kg (1.5 mL/kg of reconstituted 50 mg/mL BIG-IV solution). The BIG-IV solution may be “piggybacked” into a preexisting line if it contains either 0.9% sodium chloride injection, 2.5% dextrose in water, 5% dextrose in water, 10% dextrose in water, or 20% dextrose in water (with or without added sodium chloride). If a preexisting line must be used, BIG-IV should not be diluted more than 1:2 with any of the solutions named above.²⁹ BIG-IV is administered at an initial rate of 25 mg/kg/h (0.5 mL/kg/h of reconstituted 50 mg/mL BIG-IV solution) for the first 15 minutes, which is then increased to 50 mg/kg/h (1 mL/kg/h of reconstituted 50 mg/mL BIG-IV solution), for a total infusion time of 97.5 minutes at the recommended dose.

Other Immunoglobins

In regions where whole, equine-derived antitoxins may still be available, it is important to note that these products required sensitivity testing and potential desensitization. The package inserts should be consulted for specific procedural details for dosing and administration, particularly as titers and volumes may differ by brand.⁴¹ For prophylaxis, the recommended dose of BAT-AB for an individual who had eaten food suspected of being infected with *C. botulinum* depended on the amount of food eaten and was 1500 to 7500 IU of anti-type A and 1100 to 5500 IU of anti-type B intramuscularly (20% to 100% of one vial). This initial therapy was followed in 12 to 24 hours by the injection of a second vial if any signs or symptoms of botulism developed.⁴¹ In addition, 1000 and 5000 IU (20% to 100% of one vial) of investigational anti-type E, based on the estimated ingested quantity of botulinum toxin, had been used for type E outbreaks.⁵⁷ The BAT-AB and BAT-E treatment doses were one vial of antitoxin diluted 1:10 (vol/vol) in 0.9% sodium chloride solution and administered slowly and intravenously over 30 to 60 minutes.^{27,41} Subsequent doses could be provided intravenously every 2 to 4 hours if progression of clinical findings occurred. BAT-AB and BAT-E were administered separately.

FORMULATION AND ACQUISITION

H-BAT is supplied in either 20 mL or 50 mL single-dose vials. Despite variable vial filling of 10 to 22 mL/vial, the

amount of A, B, C, D, E, F, and G antitoxin contained per vial is fixed: more than 4500 IU of anti-A, more than 3300 IU of anti-B, more than 3000 IU of anti-C, more than 600 IU of anti-D, more than 5100 IU of anti-E, more than 3000 IU of anti-F, and more than 600 IU of anti-G.¹¹ The bulk material contains approximately 30 to 70 mg/mL protein. H-BAT contains 10% maltose and 0.03% polysorbate 80. H-BAT is stored frozen at or below 5°F (−15°C) until used. Thawed H-BAT must be maintained at 36° to 46°F (2°–8°C) and used within 36 months, or until 48 months from the manufacture date, whichever occurs earliest. H-BAT should not be refrozen. Frozen H-BAT can be thawed in a refrigerator at 36° to 46°F (2°–8°C) over approximately 14 hours. Rapid thawing can be achieved by placing at room temperature for one hour, followed by a water bath at 98.6°F (37°C) until thawed. Reconstituted H-BAT may be stored refrigerated for use within 8 to 10 hours.

BIG-IV is formulated as a 6-mL, single-use, solvent-detergent-treated, sterile vial containing 100 ± 20 mg of lyophilized immunoglobulin (primarily IgG with trace amounts of IgA and IgM), stabilized with 5% sucrose and 1% albumin (human), without preservative.^{22,29}

BAT-AB, which may be available outside of the United States, must be maintained at 36° to 46°F (2°–8°C) and not frozen. It contains phenol 0.4% as a preservative.

Medical care providers who suspect botulism should immediately call their local or state health department's emergency 24-hour telephone service to request release of botulinum antitoxin and comply with legal reporting requirements. When local and state public health authorities are unavailable, the CDC Emergency Operations Center telephone contact is 770-488-7100. The CDC controls H-BAT distribution from stocks located throughout a national network of quarantine stations. The California Infant Botulism Treatment and Prevention Program (510-231-7600) maintains the supply of botulism immune globulin for infant botulism treatment. The Biomedical Advanced Research and Development Authority (BARDA) within the US Department of Health and Human Services has obtained approximately 120,000 H-BAT doses for the Strategic National Stockpile, with anticipated delivery of 80,000 additional doses.⁵⁶

SUMMARY

- In conjunction with frequent clinical assessments and aggressive supportive care of respiratory, gastric, and urinary function, provision of botulinum antitoxin appears to decrease morbidity and mortality after typical food borne or wound botulism.
- Preliminary data suggest that early administration of licensed H-BAT decreases the duration of hospitalization, ICU utilization, and mechanical ventilation.
- Current antitoxins cannot neutralize novel botulinum neurotoxin type H.
- Licensed BIG-IV provides effective treatment for infant botulism.
- Early consultation with local health departments, the CDC Emergency Operations Center, or a regional poison center (or other comparable agencies in other parts of the world) should occur to rapidly access effective therapeutic modalities and diagnostic tests for botulism.

42 DIETING XENOBIOTICS AND REGIMENS

Jeanna M. Marraffa

Ephedrine

INTRODUCTION AND HISTORY

Obesity is a worldwide epidemic, and the United States has the largest proportion of a national population of overweight and obese individuals.¹²⁵ Nearly 68% of Americans are overweight (body mass index {BMI}, 25–29.9) and 35% are obese (BMI >30 kg/m²).^{53,123} Even more alarming, the incidence of obesity in children between the ages of 6 and 19 years has tripled in the past 30 years.^{12,124} As many as 17% of children aged 2 to 19 years of age are obese, and 31% of children are overweight.^{12,123} There are conflicting data as to the exact number of deaths attributed to obesity annually; however, all of the studies agree that obesity results in excess mortality.^{53,54} In 2009, the Centers for Disease Control and Prevention reported greater than 110,000 deaths due to obesity in the United States. The cost of obesity is staggering and is reported to be upward of \$147 billion.²⁷ Obesity is linked to numerous health risks, including type 2 diabetes, hypertension, coronary heart disease,^{12,24} metabolic syndrome,¹⁷⁰ and low back pain.¹⁴⁸ Obesity is considered a leading preventable health risk, second only to cigarette smoking. Genetic links including particular gene polymorphisms have been identified and are being pursued.¹¹⁶

Americans spend upward of \$60 billion per year on weight loss therapies and modalities. Pharmacologic interventions typically result in a 5% to 10% weight loss, although a return to baseline upon drug cessation is common.⁴⁶ Surgical interventions consistently achieve substantial weight loss, causing up to a 30% reduction in weight, but they are not without complications.^{2,20}

One of the earliest accounts of weight loss therapy dates back to 10th century Spain. King Sancho I, who was obese, underwent successful treatment with a “theriaca” thought to contain plants and possibly opioids, administered with wine and oil. In addition, he was closely supervised and treated by a physician.⁷⁹

Currently, medicinal weight loss therapies (Table 42–1) are available as prescription medications (lorcaserin, phentermine, phentermine/topiramate), nonprescription dietary supplements (Citrus aurantium, chitosan, Garcinia cambogia, caffeine), and nonprescription diet aids (orlistat). Numerous other prescription medications, including thyroid medications and metformin, have been used on an off-label basis for weight loss. Numerous xenobiotics are promoted as weight loss aids, many with no proven efficacy and some with serious toxicity.

TABLE 42–1. Available Weight Loss Xenobiotics

<i>Drug or Supplement^a</i>	<i>Mechanism of Action</i>	<i>Regulatory Status</i>	<i>Adverse Effects/Contraindications^b</i>
Sympathomimetics			
Diethylpropion (Tenuate)	Increased release of norepinephrine and dopamine	Schedule IV prescription drug	Dry mouth, tremor, insomnia, headache, agitation, palpitations, hypertension, stroke, dysrhythmias
Mazindol (Mazanor, Sanorex)	Increased release of norepinephrine and dopamine	Schedule IV prescription drug	Contraindications: monoamine oxidase inhibitor use within 14 days, glaucoma, hyperthyroidism
Phentermine (Fastin, Adipex)	Increased release of norepinephrine and dopamine	Schedule IV prescription drug	Similar to diethylpropion
Phentermine/Topiramate (Qsymia)	Increased release of norepinephrine and dopamine (phentermine); exact mechanism of action for topiramate remains speculative	Schedule IV prescription drug	Phentermine: similar to diethylpropion Topiramate: central nervous system depression; ataxia; non-anion gap metabolic acidosis Contraindication: first trimester pregnancy
Bitter orange extract (<i>Citrus aurantium</i>)	Contains synephrine and octopamine; increases thermogenesis and lipolysis	Dietary supplement	Hypertension, cerebral ischemia, myocardial ischemia, prolonged QT interval
Guarana (<i>Paullinia cupana</i>)	Contains caffeine, which may increase thermogenesis	Dietary supplement	Nausea, vomiting, insomnia, diuresis, anxiety, palpitations
Raspberry ketones	Structurally similar to synephrine; increases thermogenesis and lipolysis	Dietary supplement	Nausea, vomiting, insomnia, hypertension, tachycardia, anxiety, palpitations
Serotonergics			
Lorcaserin (Belviq)	Selective agonist at 5-HT ₄	Schedule IV prescription drug	Dizziness, headache, nausea; serotonin toxicity possible after overdose
GI Agents			
Orlistat (Xenical/Alli)	Inhibits gastric and pancreatic lipases	Prescription and nonprescription drug	Abdominal pain, oily stool, fecal urgency or incontinence; fat-soluble vitamin loss Contraindications: cholestasis, chronic malabsorption
Chitosan	Insoluble marine fiber that binds dietary fat	Dietary supplement	Decreased absorption of fat soluble vitamins Contraindications: shellfish allergy
Fibers/Other Supplements			
Glucosulfate	Expands in stomach to increase satiety	Dietary supplement	Gastrointestinal (GI) obstruction with tablet form Contraindications: abnormal GI anatomy
Garcinia cambogia	Increases fat oxidation (unproven)	Dietary supplement	None reported
Chromium picolinate	Improves blood glucose and lipids; produces fat loss (unproven)	Dietary supplement	Dermatitis, hepatitis, possibly mutagenic in high doses

^aTrade names or botanical names are given in parentheses. ^bAll serotonergics are contraindicated during pregnancy and lactation.

The history of dieting xenobiotics is checkered. A number of weight loss therapies were withdrawn or banned by the Food and Drug Administration (FDA) because of serious adverse health effects (Table 42–2). Phenylpropanolamine,⁸⁷ fenfluramine-phentermine,³⁴ and sibutramine⁸² were withdrawn from the US market. The endocannabinoid receptor antagonists (rimonabant) never reached the US market. γ -Hydroxybutyric acid (GHB) and its congeners were initially sold as dietary supplements (Chap. 83) and promoted to body builders as a means to “convert fat into muscle” as a result of the effect of GHB on growth hormone. Because of toxicity and its association with drug-facilitated sexual assault, GHB is strictly controlled as a schedule I drug, with limited availability as a schedule III drug for narcolepsy (Xyrem). Clenbuterol is a long-acting β_2 -adrenergic agonist. Because of the stimulant properties and lipolytic effects, clenbuterol is abused by body builders as an energy source and anorectic agent.⁷⁶ It has been touted by celebrities to be an effective diet aid (Chap. 40).

TABLE 42–2. Unavailable and Withdrawn Weight Loss Xenobiotics

<i>Drug or Supplement*</i>	<i>Mechanism of Action</i>	<i>Adverse Effects</i>	<i>Regulation Status, DEA Schedule, or Withdrawal Date</i>
Amphetamine	Increased release of norepinephrine and dopamine	Sympathomimetic effects, psychosis, dependence	Schedule II
Benzphetamine (Didrex)	Increased release of norepinephrine and dopamine	Sympathomimetic effects, psychosis, dependence	Schedule III
Clenbuterol	β_2 -Adrenergic agonist activity	Tachycardia, headache, nausea, vomiting; may be prolonged	Never approved
Deferipraramine (Redux)	Promotes central serotonin release and inhibits its reuptake	Valvular heart disease, primary pulmonary hypertension	Withdrawn September 1997
Dieter's teas (senna, cascara, aloe, buckthorn)	Stimulant laxative herbs that promote colonic evacuation	Diarrhea, vomiting, nausea, abdominal cramps, electrolyte disorders, dependence	FDA required label warning, June 1995
Dinitrophenol	Alters metabolism by uncoupling oxidative phosphorylation	Hyperthermia, cataracts, hepatotoxicity	Never approved
Ma-huang (<i>Ephedra sinica</i>)	Increased release of NE and dopamine	Sympathomimetic effects, psychosis	Banned by FDA, April 2004
Fenfluramine (Fenfluramin)	Increased release and decreased reuptake of serotonin	Valvular heart disease, primary pulmonary hypertension	Withdrawn September 1997
Guar gum (Cai-Ban 3000)	Hygroscopic polysaccharide swells in stomach, producing early satiety	Esophageal and small bowel obstruction, fatalities	Banned by FDA, July 1990
Lipokinetix (sodium oxalate, norephedrine, 3,5-diiodothyronine, yohimbine, caffeine)	Unknown	Acute hepatitis	FDA warning, November 2001
Phendimetrazine (Adipost, Bontril)	Increased release of NE and dopamine	Sympathomimetic effects, psychosis	Schedule III
Phenylpropanolamine (Desatrim, Acatrim)	α_1 -Adrenergic agonist	Sympathomimetic effects, headache, hypertension, myocardial infarction, intracranial hemorrhage	Withdrawn November 2000
Rimonabant (Acomplia)	Endocannabinoid receptor antagonist	Anxiety, nausea, diarrhea, dizziness; increased suicidality and depression	Never approved in the United States; withdrawn from European market in 2011
Sibutramine (Meridia)	Inhibits reuptake of serotonin and norepinephrine	Increase in cardiovascular toxicity; increase in nonfatal myocardial infarction; increase in nonfatal stroke	Withdrawn October 2010

*Trade names or botanical names as appropriate are given in parentheses.

DEA = Drug Enforcement Administration; FDA = Food and Drug Administration.

For the first time in many years, two new pharmaceutical preparations received FDA approval for weight loss in 2012. Phentermine/topiramate (Qsymia) and lorcaserin (Belviq) received FDA approval and became available late in 2012. Pharmacologically different, they show promise in the weight loss drug armamentarium. Other new pharmaceuticals are currently being investigated and likely to be presented to the FDA for consideration.

PATHOPHYSIOLOGY

Dieting xenobiotics can be divided into classes based on one or more of the following mechanisms of action: (1) appetite suppression (anorectics), (2) alteration of food absorption or elimination, or (3) increased energy expenditure. The hypothalamus is the key site in the brain that regulates food intake, energy expenditure, satiety, and metabolism. Sympathomimetics, serotonergics, dinitrophenol, and bupropion/naltrexone all work pharmacologically on the hypothalamus for weight loss. The endocannabinoid receptors, namely CB1, are located in the brain and in the intestines, liver, pancreas, adipose tissue, and skeletal muscle.

Endocannabinoid receptor antagonists bind to CB1 receptors and cause weight loss via different mechanisms. Neurohormonal approaches at targeting weight loss are under investigation, with specific focus on leptin, amylin, ghrelin, and glucagon-like peptide-1 (GLP-1). Leptin is secreted from fat proportionate to the amount of lipids contained in the

adipocyte, with women secreting more leptin than men. Leptin acts on the hypothalamus to decrease food intake, enhancing the metabolic rate and energy expenditure. Ghrelin is secreted by the stomach, and concentrations increase following fasting and just prior to meals. Ghrelin stimulates the hypothalamus and stimulates food intake. GLP-1 enhances glucose-induced insulin secretion while suppressing glucagon release (Fig. 42–1).^{47,57}

Sympathomimetics, serotonergics, dinitrophenol and bupropion/naltrexone work on the hypothalamus. Orlistat works in the stomach and decreases absorption. Endocannabinoid receptor antagonists work at various sites on central and peripheral CB1 receptors (CB1[®]). Ghrelin antagonists decrease appetite through the hypothalamus. Peptide YY inhibits appetite stimulation at the hypothalamus. Leptin increases metabolic rate and energy expenditure and decreases food intake.

FIGURE 42–1. Endocrine and neuroendocrine pathways of obesity and weight loss regimens. Systems regulating food ingestion and energy balance are interconnected and regulated. The hypothalamus regulates food intake, satiety, energy expenditure, and metabolism. Adipose tissue functions for glucose uptake and conversion; lipogenesis and lipolysis; β

oxidation of fatty acids; and release of leptin, adiponectin, and interleukin-6, all of which regulate energy balance.

Although there has been improvement and advancements in the understanding and treatment of obesity, significant challenges remain. The ideal xenobiotic for weight loss has yet to be identified.

SYMPATHOMIMETICS

Although controversial, certain sympathomimetic amines still carry official indications for short-term weight reduction (Table 42–1). Sympathomimetic amines share a β -phenylethylamine parent structure and include phentermine, diethylpropion, and mazindol, which are restricted as schedule IV drugs and carry warnings that advise prescribers to limit use to only a few weeks. Phentermine/topiramate extended release (Qsymia) was recently approved.^{6,11} Regardless of their source and legal status, sympathomimetics generally share a spectrum of toxicity and produce adverse effects similar to amphetamines (Chap. 76).

Pharmacology

Sympathomimetic amines that act at α - and β -adrenergic receptors are clinically effective in promoting weight loss but have numerous side effects that limit their clinical use. Soon after its introduction as a pharmaceutical for nasal congestion in the 1930s, the prototype sympathomimetic drug amphetamine (Fig. 42–2) was noted to cause weight loss (Chap. 76). The weight loss effect of amphetamine was also readily apparent in early animal studies, although tolerance to the anorectic effects was also noted.¹⁵⁸ The primary mechanism of action of the weight loss effects of sympathomimetic drugs is central nervous system (CNS) stimulation, resulting from increased release of norepinephrine and dopamine.¹⁵⁵ The effects include direct suppression of the appetite center in the hypothalamus and reduced taste and olfactory acuity, leading to decreased interest in food. Increased energy and euphoriant effects of the stimulants also contribute to weight loss. However, tachyphylaxis occurs, and the rate of weight loss diminishes within a few weeks of initiating therapy.⁴⁹ Significant side effects and abuse potential severely limit the therapeutic use of this class of drugs.

FIGURE 42–2. Sympathomimetic amines formerly and currently used for weight loss.

Adverse Effects

Absence of polar hydroxyl groups from a sympathomimetic amine increases its lipophilicity; therefore, unsubstituted or predominantly alkyl group substituted compounds (eg, amphetamine, ephedrine, phenylpropanolamine {PPA}) have greater CNS activity. Mild cardiovascular and CNS stimulant effects include headache, tremor, sweating, palpitations, and insomnia. More severe effects that may occur after overdose of sympathomimetic amines include anxiety, agitation, psychosis, seizures, palpitations, and chest pain.^{145,164}

Hypertension is common following overdose and occasionally following therapeutic use. Patients may present with confusion and altered mental status as a result of hypertensive encephalopathy. Reflex bradycardia after exposure to xenobiotics with predominantly α -adrenergic agonist effects may accompany the hypertension and provides a clue to the diagnosis. Children may be at especially high risk for hypertensive episodes because of the relatively significant dose per kilogram of body weight from even a single tablet. Other manifestations include chest pain, palpitations, tachycardia, syncope, hypertension, mania, psychosis, convulsions, and coronary vasospasm.^{129,180}

Clinically significant hypertension should be treated aggressively with either phentolamine, a rapidly acting α -adrenergic antagonist or nicardipine. Analogous to the management of cocaine toxicity, β -adrenergic antagonists should be avoided because the resultant unopposed α -adrenergic agonist effects may lead to greater vasoconstriction and hypertension.⁵ Agitation, tachycardia, and seizures should be treated initially with benzodiazepines.

Herbal Sympathomimetic Products

Since ephedra was banned, herbal weight loss supplements have been reformulated. Many now contain an extract of bitter orange (*C. aurantium*), a natural source of the sympathomimetic amine synephrine, often in combination with caffeine, theophylline, willow bark (containing salicylates), diuretics, and other constituents. The dried fruit peel of bitter orange is a traditional remedy for gastrointestinal ailments. The predominant constituents, p-synephrine (Fig. 42–2) and octopamine, are structurally similar to epinephrine and norepinephrine. The isomer m-synephrine (phenylephrine or Neo-Synephrine) is used extensively as a vasopressor and nasal decongestant. Although the physiologic actions of synephrine are not fully characterized, it appears to interact with amine receptors in the brain and acts at peripheral α_1 -adrenergic receptors, resulting in vasoconstriction and increased blood pressure.⁵⁸ Some evidence indicates that synephrine may also have β_2 -adrenergic agonist activity,¹³⁹ which could increase lipolysis. β_2 -Adrenergic agonists were found to have remarkable antiobesity effects in rodents; however, effects in human are not as profound. Octopamine stimulates lipolysis in rats, hamsters, and dogs, although this effect was not seen in human fat cells.^{24,58}

Nearly 2% of 4140 Californians surveyed had used a *C. aurantium*-containing product several times a week.⁹² Adverse effects associated with use of *C. aurantium*-containing weight loss products are reported, including tachydysrhythmias,⁵² cerebral ischemia in a 38 year-old man,¹⁶ exercise induced syncope, and QTc interval prolongation in a 22 year-old woman,¹¹⁹ and a possible case of myocardial infarction in a 55 year-old woman.¹²¹

Raspberry ketone, 4-(4-hydroxyphenyl)-2-butanone, is promoted to induce weight loss and is available as a supplement. Structurally similar to synephrine, its purported effects on weight loss are similar. The amount of raspberry ketone in a typical dose of a dietary supplement is equal to the amount derived from 40 kilograms of raspberries. Studies in rats show an increase in lipolysis and alteration in lipid metabolism.^{117,129} Toxicity is not yet described in the literature, although clinical effects would be expected to be similar to other sympathomimetics.

Phentermine/Topiramate

Phentermine is a sympathomimetic that still retains an FDA indication for short-term weight loss. It increases release of norepinephrine, which serves as an appetite suppressant via the effects on the hypothalamus. Topiramate has been on the US market for years for a variety of conditions including seizure disorder and migraine headaches. Weight loss is a demonstrated side effect of topiramate when used for these indications.⁸⁹ The mechanism of weight loss induced by topiramate remains speculative and is likely a combination of decreased caloric intake, increased energy expenditure, and decreased energy efficiency.^{6,59}

Phentermine/topiramate controlled release (Qsymia) is approved for long term management of weight loss. The FDA recommends discontinuation if 5% of body weight is not lost within 24 weeks of therapy initiation.^{32,33} The clinical trials evaluating the efficacy of phentermine/topiramate, were short term studies performed in approximately 4000 patients.^{6,11,59} In all of these trials, there was a substantial decline in body fat (upward of 10%) as well as improvement in other metabolic parameters, including lipid control and glucose regulation. In addition, blood pressure declined in all three trials. Adverse events appeared mild, although there were increases in heart rate and complaints of somnolence. There appears to be an increased risk of congenital malformations, particularly orofacial clefts, when taken during the first trimester of pregnancy.⁵⁷ Because topiramate is a carbonic anhydrase inhibitor, it can decrease serum bicarbonate resulting in a nonanion gap metabolic acidosis.¹⁴⁶

Although there have been no documented cases of overdose of this combination product, its toxicity can be extrapolated from the known toxicities of the individual components. Phentermine toxicity is described in detail above. Topiramate toxicity causes CNS depression, dizziness, ataxia, a nonanion gap metabolic acidosis, and hypokalemia^{17,106,146} (Chap. 48).

SEROTONERGICS

Xenobiotics that affect central release and reuptake of serotonin are approved for a number of indications, including depression, anxiety, nicotine addiction, migraine headache, and premenstrual dysphoric syndrome. Serotonin is believed to have a role in appetite suppression, which is due to the effect on the hypothalamic serotonin 5-HT_{2C} receptor, as well as the 5-HT_{1A}, 5-HT_{1B}, and 5-HT₆ receptors.^{67–69,71} Serotonin receptor effects may also enhance energy expenditure. The serotonin agonists have been associated with cardiac valvulopathy (5-HT_{2B} receptor), hallucinations (5-HT_{2A} receptor),

and pulmonary hypertension (5-HT_{1B}), as well as serotonin toxicity.

Lorcaserin (Belviq), approved by the FDA in 2012, is a novel selective agonist at the 5-HT_{2C} receptor.^{9,50,80,109} This novel selectivity for the 5-HT_{2C} receptor conceivably may permit weight loss with minimal risk of significant toxicity as recognized with other serotonergics.⁶⁸ Lorcaserin neither stimulates the release of norepinephrine, dopamine, or serotonin, nor does it inhibit the reuptake of these neurotransmitters.^{67,68}

Lorcaserin 10 mg twice daily showed a significant reduction in body fat (5.8 ± 0.2 kg) compared to placebo (2.2 ± 0.1 kg) after 52 weeks of therapy in 3182 subjects. In addition to the weight loss achieved in 1 year, the subjects maintained their body weight for 1 year.¹⁵³ No increase in the incidence of cardiac valvulopathy was demonstrated in the 2-year follow up in the subjects receiving lorcaserin.¹⁵³ In all of the clinical trials, the adverse events were minimal and included dizziness, headache, and nausea.^{50,75,84,136,153}

There have been no cases of overdose documented to date. Expected clinical toxicity includes nausea, vomiting, dizziness, and headache. In large overdoses, receptor selectivity is typically lost, suggesting that large overdoses of lorcaserin would cause effects from agonism at other serotonergic receptors. Serotonin toxicity may occur after overdose (Chap. 75).

Management of the toxic effects mediated by serotonin receptors should address the specific clinical effects. Benzodiazepines may be useful for tachycardia and hypertension. Rapid identification and management of serotonin toxicity is essential to prevent associated morbidity and mortality (Chap. 75).

XENOBIOTICS THAT ALTER FOOD ABSORPTION, METABOLISM, AND ELIMINATION

Fat Absorption Blockers

Orlistat (Xenical) was approved by the FDA in 1999 for treatment of obesity. In 2007, orlistat (Alli) became available as a nonprescription formulation. The availability may pose an abuse potential for patients with eating disorders, and abuse should be considered in patients presenting with related adverse events. Orlistat is the only FDA approved drug that alters the absorption, distribution, and metabolism of food. Orlistat is a potent inhibitor of gastric and pancreatic lipase, thus reducing lipolysis and increasing fecal fat excretion.²⁵ The drug is not systemically absorbed but exerts its effects locally in the gastrointestinal tract. It inhibits hydrolysis of dietary triglycerides and reduces absorption of the products of lipolysis, monoglycerides, and free fatty acids. Several clinical trials demonstrate that orlistat reduces gastrointestinal fat absorption by as much as 30%.¹⁷⁷ When taken in association with a calorie restricted diet, weight loss of approximately 10% body weight can be achieved in 1 year.¹⁵¹ Orlistat is associated with a modestly lower weight gain over a 3 year period when compared to placebo (4.6 kg versus 7 kg, respectively).¹³⁷

Orlistat should be taken only in conjunction with meals that have a high fat content; it should not be consumed in the absence of food intake. Adverse effects correlate with the amount of dietary fat consumption and include abdominal pain, oily stool, fecal incontinence, fecal urgency, flatus, and increased defecation. Systemic effects, which are rare due to the lack of systemic absorption,^{51,115,162} include cholestatic hepatitis and hepatocellular necrosis,^{115,162} but there is an inconsistent demonstration of a temporal relationship. In a cohort of nearly 16,000 patients in England, although there were no cases of serious hepatotoxicity, there were reports of aminotransferase elevations. Two of the cases were deemed as causally related to orlistat, and one had evidence of aminotransferase elevations and elevations on rechallenge.¹³² Concomitant use of natural fibers (6 g of psyllium mucilloid dissolved in water) may reduce the gastrointestinal side effects of orlistat.²⁶ Because orlistat reduces absorption of fat soluble food constituents, daily ingestion of a multivitamin supplement containing vitamins A, D, and K, and β -carotene is advised to prevent resultant deficiency. Pancreatitis⁴ and oxalate nephropathy¹⁴⁹ are rarely reported after orlistat use. Currently, there are no reported intentional overdoses of orlistat. There are limited data regarding unintentional pediatric exposure to orlistat, and the toxicity appears to be limited to mild gastrointestinal effects.¹²² In overdose and/or misuse, treatment should be responsive to clinical manifestations.

Chitosan is a weight loss dietary supplement derived from exoskeletons of marine crustaceans. It is thought to act similarly to orlistat by binding to dietary lipids in the gastrointestinal tract and reducing breakdown and absorption of fat. Animal models describe an increase in fecal fat excretion in rats administered chitosan when they are fed high-fat diets.⁴¹ The efficacy of chitosan in humans is disputed.^{60,112,113} Some evidence indicates that chitosan may decrease total serum cholesterol concentration in overweight people, but the majority of clinical studies indicate chitosan is ineffective for weight loss in the absence of dietary and lifestyle modifications.¹⁴⁷ It is estimated that in the presence of chitosan, it would take more than 7 months to lose 1 pound of body fat.⁶⁰ Chitosan is contraindicated in people with shellfish allergy.

Dietary Fibers

Glucomannan is a dietary fiber consisting of glucose and mannose, which is derived from konjac root, a traditional Japanese food. Edible forms of glucomannan include konjac jelly and konjac flour, which are mixed with liquid prior to ingestion. Purified glucomannan is available in capsule form and is found in various proprietary products marketed for weight loss. On contact with water, glucomannan swells to approximately 200 times its original dry volume, turning into a viscous liquid. It lowers blood cholesterol and glucose concentrations and decreases systolic blood pressure,^{7,167} but significant weight loss benefits are not demonstrated.⁹⁵ Following several reports of esophageal obstruction, glucomannan tablets were withdrawn from the market in Australia in 1985.⁷³ Serious adverse effects are not described with encapsulated glucomannan, presumably because slower dissolution allows for gastrointestinal transit prior to expansion. Glucomannan capsules are available as a nutritional supplement in the United States, although adequate safety and efficacy studies are not published.

Dinitrophenol

One of the earliest attempts at a pharmaceutical treatment for obesity was 2,4-dinitrophenol (DNP), which was popularized as a weight loss adjuvant in the 1930s.^{64,160} This chemical, which is used in dyes, wood preservatives, herbicides, and explosives, was never approved as a drug product. DNP was legally available as a dietary supplement prior to enactment of the US Federal Food, Drug, and Cosmetic Act of 1938 and thus remained legal. By increasing metabolic energy expenditure, it reportedly produces weight loss of 1 to 2 pounds per week in doses of 200 to 300 mg per day.^{31,64} DNP increases metabolic work by uncoupling oxidative phosphorylation in the mitochondria. Through this mechanism, the hydrogen ion gradient that allows ATP synthesis is destroyed and ATP production is stopped, though oxidative metabolism in the Krebs cycle continues (Chap. 13). This mechanism results in inefficient substrate utilization, and the resulting energy loss is dissipated as heat. This wastes calories but also elevates temperature and, occasionally, life-threatening hyperthermia can occur.¹⁵⁹ In fact, DNP was reportedly administered to Russian soldiers during World War II to keep them warm during winter battles.⁶⁴ Symptoms related to DNP toxicity include malaise, skin rash, headache, diaphoresis, thirst, and dyspnea. Severe toxic effects include hyperthermia, hepatotoxicity, agranulocytosis, respiratory failure, coma, and death.^{15,96,159} Delayed-onset cataracts were a frequent and serious complication of DNP use.¹⁵

Epidemic use of DNP occurred in Texas in the 1980s when industrial DNP was used at a physician's weight loss center. The physician distributed DNP under the trade name, Mitcal. The fatality of a wrestler following an intentional overdose in 1984 led a Texas court to stop the use of this practice.⁹⁶ DNP continues to reappear sporadically as a weight loss treatment, and cases of serious toxicity still are reported.^{64,127} Management should emphasize rapid cooling (Chap. 30). Benzodiazepines should also be used as an adjunct therapy for management of delirium and seizures.

Endocannabinoid Receptor Antagonists

In the past decade, the endocannabinoid system (ECS) and its involvement in weight loss sparked excitement and potential for novel xenobiotics. Endocannabinoids, which are the natural ligand for the cannabinoid receptor, have diverse effects on metabolic functions.⁷⁷ The ECS contributes to the regulation of food intake, body weight, and energy balance, and it may have a role in inflammation and neuropathic pain.^{83,141,169,174} It has long been known that tetrahydrocannabinol, the active principle in marijuana (*Cannabis sativa*), stimulates appetite and is an effective antiemetic (Chap. 77).^{29,131}

Several CB1 receptor antagonists showed promise in both animal and human studies of weight loss. Rimonabant was approved for therapeutic use in Europe and clinical trials in the United States were performed. Clinical studies note that these xenobiotics showed a significant and sustained reduction in body weight.¹³⁵ There was also improvement in insulin resistance with a decline in plasma leptin, insulin, and free fatty acid concentrations, presumably due to the upregulation of the peripheral ECS system in diabetes.^{74,140} In the clinical trials there was a significant increase in adverse events, including anxiety and depression in the rimonabant groups. This led to a delay in the FDA's approving this product for therapeutic use. Shortly after approval in Europe, it became evident that the effects of anxiety and depression were far greater than initially expected. Rimonabant was never approved by the FDA, and other Phase III studies, including those involving other endocannabinoid receptor antagonists (eg, tranabant), were terminated early. Rimonabant was removed

from the European market. Centrally acting CB1 antagonists proved to have an unfavorable risk–benefit relationship. However, peripherally acting CB1 antagonists have shown some promise for weight loss, and further research is currently underway.^{48,65}

Naltrexone/Bupropion

Naltrexone is an opioid receptor antagonist that is currently approved by the FDA for the treatment of alcohol and opioid dependence.¹⁶⁸ Bupropion is a norepinephrine and dopamine reuptake inhibitor that is approved for both depression and smoking cessation, and it is known to cause weight loss at therapeutic doses. The combination of naltrexone and bupropion is effective in inducing weight loss and is beneficial in other addictive disorders. The mechanisms by which naltrexone/bupropion cause weight loss is not completely understood.¹⁶⁸ Proopiomelanocortin (POMC)-producing neurons in the hypothalamus are stimulated with bupropion, and naltrexone inhibits the opioid mediated POMC autoinhibition. This combination of stimulation and inhibition of the negative feedback loop on POMC neurons is believed to facilitate ongoing weight loss. Additionally, it is believed that there is synergism with naltrexone and bupropion in midbrain dopamine areas resulting in decreased food intake, presumably through modulation of mesolimbic reward systems.^{63,86,168}

This potential synergistic effect has resulted in promising effects. A new drug application for the combination product of Naltrexone SR/Bupropion SR (Contrave/NB32) was submitted to the FDA in 2010.¹³ The Contrave Obesity Research Program consists of four 56-week, randomized, double-blind, placebo-controlled Phase III trials.^{63,168} The combination of naltrexone plus bupropion in these studies demonstrated a 5% to 15% weight reduction.¹⁶⁸ The naltrexone SR 32 mg/bupropion 360 mg/day per arm resulted in significantly greater weight loss and had improvements in markers of cardiovascular risk. The combination was generally well tolerated, with nausea and headache most frequently reported.^{63,168} There was no increased depression or suicidality in the treatment groups.

The FDA has mandated a clinical trial evaluating cardiovascular risk of naltrexone SR 32 mg/bupropion SR 360 mg in subjects with underlying cardiovascular risk factors. The status of the FDA approval of this combination therapy is pending the results of the current clinical trial. It is unclear if the combination drug will receive FDA approval despite its promising results on weight reduction.

Adverse events from this product result from the known toxicity of each individual xenobiotic. Naltrexone is generally expected to be safe and well tolerated in opioid naive patients; however, it will cause prolonged opioid withdrawal symptoms in opioid tolerant patients and will significantly reduce the efficacy of opioids if they are required. Bupropion toxicity is well described in the literature. Seizures may occur after bupropion at doses greater than 450 mg per day.^{38,145} The amount of bupropion available in this formulation is of particular concern as is the potential for misuse/overdose. Bupropion toxicity is discussed in detail in [Chap. 75](#).

Alternative Pharmaceutical Approaches

In an attempt to find the perfect therapeutic alternative for weight loss, there is an continuing approach to utilize currently approved xenobiotics for weight loss. Similar to topiramate, xenobiotics that are known to cause weight loss at therapeutic doses such as metformin, bupropion, and zonisamide, continue to be investigated for both label and off label use. Combination therapy aimed at multiple systems likely will prove most efficacious. Although these xenobiotics may provide a beneficial weight loss, each of them has their own inherent toxicities. Metformin can cause a metabolic acidosis with elevated lactate concentration, particularly in patients with underlying kidney dysfunction and after large intentional overdoses ([Chap. 53](#)). Zonisamide, an adjunct anticonvulsant that is not used commonly, is associated with adverse events including CNS depression and hypersensitivity^{120,175} ([Chap. 48](#)).

Future Targets for Xenobiotic Development

The desire to identify new biochemical pathways and pharmacologic approaches to weight loss began in antiquity. Research continues to evolve in an ongoing effort to determine the underlying etiology of obesity as well as develop new, more advanced pharmacologic interventions ([Table 42–3](#)).^{3,29,69} Gut peptides play an important physiologic role in normal gastrointestinal functions, including cessation of meals. Some gut peptides affect feeding control and show promise in the treatment of obesity.^{36,69,108,116}

TABLE 42–3. Potential Future of Xenobiotics for Obesity

Drug Name	Drug Class	FDA Approval Status	FDA Approved Indication	Route of Administration
Pramlintide	Synthetic analog of amylin	Approved	Type 1 diabetes	Subcutaneous
Metreleptin	Recombinant analog of leptin	Phase III	N/A	Subcutaneous
Exenatide (Byetta); extended-release exenatide (Bydureon)	Glucagonlike peptide-1 agonist	Approved	Type 2 diabetes	Subcutaneous
PYY 3-36	Peptide YY	Phase II	N/A	Intranasal
MOX-B11	Ghrelin antagonist	Phase I	N/A	Subcutaneous
GSK-598809	Dopamine antagonist	Phase I	N/A	Oral

FDA = Food and Drug Administration.

Leptin and the leptin gene are being explored as a basis for obesity and as a therapeutic strategy.^{28,78} Much of the enthusiasm about the potential role for leptin as an antiobesity therapy has subsided because leptin administration does not induce the expected response on weight control and is transient.^{134,142,161} In fact, obese people have elevated leptin concentrations, and obesity is believed to cause leptin resistance in the brain.⁴⁷ Amylin is cosecreted from the β islet cells in the pancreas and contributes to short-term energy regulation. The combination of leptin and amylin reduce food intake and body weight even in the setting of leptin resistance.¹⁶¹ Pramlintide acetate (a synthetic analog of amylin) and metreleptin (a recombinant analog of leptin) combination therapy has been studied in animals and humans for weight loss with promising results. The combination therapy was stalled in Phase II clinical trials because of safety concerns. It remains unclear if this potential combination therapy and novel approach will be continued in drug development.¹⁶¹ This suggests that combination therapy in the management of obesity is increasingly important.

Ghrelin antagonists are also suggested as a possible adjunct therapy for weight loss. Ghrelin is a growth hormone releasing agent produced by the stomach that stimulates appetite.^{93,94,163} Data suggest that ghrelin and leptin work together to stimulate food consumption.^{39,107} Ghrelin antagonists may decrease the increased appetite that often occurs with dietary modifications for weight loss and such agents are under investigation.¹¹⁶ Neuropeptide Y, a peptide found in the arcuate and paraventricular nucleus of the hypothalamus, is a potent central appetite stimulant.

GLP-1 is produced in the brain and distal intestine. During a meal, GLP-1 concentrations increase and remain elevated for several hours after. GLP-1 inhibits food intake, inhibits glucagon secretion, decreases gastric acid secretion, and delays gastric emptying. Exendin-4, extracted from the venom of the Gila monster, is a pharmaceutically available GLP-1 agonist, exenatide (Byetta), and is approved by the FDA for diabetes mellitus. It decreases food intake and produces a 2 to 5 kilogram sustained weight loss. Extended release exenatide (Bydureon) is available and has an FDA approved indication for type 2 diabetes. It is dosed every 7 days, and although it does not have an FDA approved indication for weight loss, it will likely be used off-label for weight loss. Acute overdoses of exenatide are rarely reported; however, the potential for hypoglycemia remains a significant concern, although it has not yet been reported.^{30,31}

Peptide YY is similar to GLP-1 and has been investigated for weight loss. Preliminary data suggest that intranasal peptide YY failed to induce a significant body weight reduction when compared to placebo and had a high incidence of nausea and vomiting.¹¹⁶

Because β_2 -adrenergic receptors mediate lipolysis in adipose tissue, β_2 -selective agonists also are under investigation to enhance weight loss.¹³⁹ Future drug therapy may target these genes, receptors, and proteins to modify metabolism. As obesity research proceeds and the biologic basis for obesity is defined, new approaches and mechanisms for therapy may be identified.¹⁹

Hypocaloric Diets and Cathartic/Emetic Abuse

Starvation, as well as abuse of laxatives, syrup of ipecac, diuretics, and anorectics, has led to morbidity and mortality, often in young patients.^{56,81} Fad diets and laxative abuse should be strongly considered in young people with unexplained salt and water depletion, syncope, hypokalemia, and metabolic alkalosis. A variety of extreme calorie-restricted diets resulting in profound weight loss were very popular in the late 1970s, but reports of a possible association between these diets and sudden death followed.¹⁵⁰ Myocardial atrophy was a consistent finding on autopsy. Torsade de pointes and other ventricular dysrhythmias may have occurred as a result of hypokalemia^{150,154} and protein-calorie malnutrition are proposed as causes of death.^{45,150, 154}

Following the negative reports and FDA warnings, the enthusiasm for liquid protein diets waned. Several current diets (Atkin's plan, South Beach diet) advocate intake of high protein, high fat, and low carbohydrates while allowing unlimited amounts of meat, fish, eggs, and cheese. Lack of carbohydrates induces ketosis, which results in salt and water depletion,

giving the user the appearance of rapid weight loss. With rehydration and resumption of a normal diet, weight gain generally occurs. In addition, salt and water depletion may cause orthostatic hypotension and ureterolithiasis. Atherosclerosis and hypercholesterolemia may occur as a result of substitution of high-calorie, high fat foods for carbohydrates. Despite the rapid weight loss early on with these diets, once carbohydrates are reintroduced, weight gain occurs rapidly and significantly.⁴⁶

Dieter's teas that contain combinations of herbal laxatives, including senna and Cascara sagrada, can produce profound diarrhea, salt and water depletion, and hypokalemia. They are associated with sudden death, presumably as a result of cardiac dysrhythmias. Despite FDA warnings of the dangers of these weight loss regimens, dieter's teas remain available in retail stores that sell nutritional supplements and are easily accessible to adolescents.

Chronic laxative use can result in an atonic colon ("cathartic bowel") and development of tolerance, with the subsequent need to increase dosing to achieve catharsis. Because cathartics do not decrease food absorption, they have limited effects on weight control.¹⁰ Various test methods can be used to detect laxative abuse.⁴⁰ Phenolphthalein can be detected as a pink or red coloration to stool or urine following alkalinization. Colonoscopy reveals the benign, pathognomonic "melanosis coli," the dark staining of the colonic mucosa secondary to anthraquinone laxative abuse. The combination of misuse/abuse of laxatives in conjunction with orlistat has the potential to cause severe diarrhea and subsequent fluid and electrolyte imbalances. Now that orlistat is readily available, there is a greater likelihood of these two xenobiotics being used together.³⁵

Chronic use of syrup of ipecac to induce emesis by patients with eating disorders, such as bulimia nervosa, leads to the development of cardiomyopathy, subsequent dysrhythmias, and death.^{56,128} Emetine, a component of syrup of ipecac, is the alkaloid responsible for the severe myopathy. Chronic administration of syrup of ipecac results in tolerance to the emetic effects and increased systemic absorption of emetine.¹²⁸ Emetine can be detected in serum by high pressure liquid chromatography or thin-layer chromatography. It persists for weeks to months after chronic ingestion. In 2003, an FDA advisory committee recommended that the nonprescription drug status of syrup of ipecac be rescinded because of its use by patients with bulimic disorders.

OTHER HERBAL REMEDIES

Several herbal remedies for weight loss have resulted in serious toxicity. In France, germander (*Teucrium chamaedrys*) supplements taken for weight loss resulted in seven cases of hepatotoxicity.⁹⁹ A "slimming regimen" first prescribed in a weight loss clinic in Belgium produced an epidemic of progressive kidney disease, known as Chinese herb nephropathy, when botanical misidentification led to the substitution of *Stephania tetrandra* with the nephrotoxic plant *Aristolochia fangji*.¹⁶⁵ The toxic constituent, identified as aristolochic acid, has been implicated in numerous cases of kidney failure and urothelial carcinoma.¹⁰⁴ A case of profound digitalis toxicity occurred with a laxative regimen contaminated with *Digitalis lanata*.¹⁵² Contamination of herbal products remains a concern today due to the lack of standardization of manufacturing processes. Until regulation of herbal products is improved and manufacturing practices worldwide are standardized, sporadic reports of herb-related toxicity likely will continue ([Chaps. 28 and 45](#)).

WITHDRAWN XENOBIOTICS

Sympathomimetics

PPA, a sympathomimetic amine ([Fig. 42–2](#)), was available until 2000 as a nonprescription diet aid (eg, Dexatrim, Acutrim). It is both a direct-acting xenobiotic, via stimulation of α -adrenergic receptors, and an indirect-acting xenobiotic, through release of norepinephrine. Both of these actions cause a net increase in blood pressure when given in high doses. PPA-induced anorexia is mediated via α -adrenergic receptors in the hypothalamus.¹⁷² PPA was voluntarily withdrawn after its use was linked to increased risk of hemorrhagic stroke in women.⁸²

Reported toxicity associated with PPA generally results from severe hypertension.¹³⁰ A comprehensive review of more than 100 case reports of adverse drug effects involving PPA revealed 24 intracranial hemorrhages, 8 seizures, and 8 fatalities between 1965 and 1990.^{62,97} Some adverse events occurred following ingestion of diet preparations that contained both PPA and caffeine, which have pharmacokinetic and pharmacodynamic interactions.^{90,98} Cardiac toxicity, although less common, was reported in two young patients who suffered myocardial injury following therapeutic daily dosing in one and acute overdose in the other.¹⁰¹

Ephedrine

Ephedra (*Ephedra sinica*), or Ma-huang, is a plant that contains six sympathomimetic amines, known collectively as ephedra alkaloids. The two primary alkaloids are ephedrine and pseudoephedrine ([Fig. 42–2](#)). Ephedra was popular as a

weight loss dietary supplement until the FDA banned ephedra-containing products in April 2004 because of cases of serious cardiovascular toxicity^{72,176} and acute hepatitis.¹¹⁸ In a review of 140 adverse events reported to MedWatch following use of ephedra, 31% of the cases were considered to be definitely or probably related to the use of ephedra supplements, including four strokes, five cardiac arrests, two myocardial infarctions, and three fatalities.⁷² In 2005, there was concern that the FDA ban would be overturned and ephedra would once again be available. But, in 2006, the US Court of Appeals upheld the FDA's final rule to ban ephedra. Despite this ban, ephedra still can be obtained from practitioners of complementary medicine as a traditional Chinese herbal medicine for short-term treatment of wheezing and nasal congestion associated with asthma, allergies, and colds. Synthetic ephedrine is still available, behind the pharmacy counter, as a nonprescription medication (eg, Primatene tablets) for asthma.

Serotonergics

Sibutramine blocks the reuptake of both serotonin and norepinephrine, but it does not promote neuronal release of serotonin. Its clinical effects include reduced appetite and increased satiety. Its effectiveness in producing weight loss was demonstrated in several randomized, double-blind studies.^{37,42,100,105} It also decreased binge-eating when compared to placebo.¹⁷³

Shortly after approval, reports of serious adverse events, including cardiovascular toxicity, emerged. Sibutramine use was associated with psychosis,^{14,103,157} hypertension, cardiac ischemia, dysrhythmias,¹³² and death.¹³² The increased risk of nonfatal myocardial infarction and nonfatal stroke in patients led to the withdrawal of sibutramine from the US market in the fall of 2010.⁸²

The serotonergics dexfenfluramine (Redux) and fenfluramine (Pondimin), used in the treatment of obesity, were withdrawn because of postmarketing reports of serious cardiac effects associated with their therapeutic use.^{18,21,34,44,171} The diet drug combination known as Fen-Phen (fenfluramine and phentermine {an amphetamine derivative}) was popular in the 1990s because of the presumed improved side-effect profile and efficacy achieved with lower doses of each drug. This drug combination was never approved by the FDA for treatment of obesity. Because of an unusual and serious cardiac valvulopathy in women taking Fen-Phen, fenfluramine was withdrawn from the market in 1997.³⁴ All of the women presented with new heart murmurs and either right- or left-sided valvular abnormalities. Eight of the 24 women also developed pulmonary hypertension. Several required cardiac surgery and were found to have plaque-like encasement of the leaflets and chordae, with preservation of valvular structure. These pathologic findings are identical to those described in patients with ergotamine-induced valvular disease and in those with carcinoid valvulopathy. Although subsequent studies confirmed this association, the reported magnitude of risk associated with these drugs has varied.^{85,88,171} Regression of these valvular lesions with cessation of the drugs is reported,²² and limited evidence indicates that the valvular effects are milder than initially described.⁶¹

Primary pulmonary hypertension has been described in association with fenfluramine and dexfenfluramine since 1981.^{8,21,44,111,138} Primary pulmonary hypertension in association with another anorectic, aminorex fumarate, was previously reported in Europe.⁶⁶ In one multicenter case control study of patients with primary pulmonary hypertension, use of anorectics such as dexfenfluramine and fenfluramine for more than 3 months was associated with a 30-fold increased risk of primary pulmonary hypertension in these patients compared with nonusers.¹ Several theories are proposed to explain the mechanism of pulmonary toxicity of these anorectics,²¹ namely, serotonin-mediated constriction of pulmonary arteries,¹¹⁰ serotonin-mediated platelet aggregation, and vasoconstriction in the lungs leading to microembolization, elevated pulmonary vascular resistance, and pulmonary hypertension.¹¹¹

Guar Gum

Guar gum is derived from the bean of the *Cyamopsis psorabides* plant and is a hygroscopic polysaccharide that expands 10- to 20-fold in the stomach, forming a gelatinous mass. The purpose of ingesting guar was to cause gastric distension and create the sensation of satiety, thereby decreasing appetite and food intake. Unfortunately, the use of guar gum resulted in numerous cases of esophageal and small bowel obstruction in patients with both preexisting anatomical lesions such as strictures and in individuals with normal gastrointestinal anatomy. It was withdrawn from the market in 1992.¹⁰²

BARIATRIC SURGERY

Although not a specific toxicologic concern, it is imperative to mention surgical interventions for management of obesity. Surgical interventions to manage obesity have increased in frequency over the past years and may provide a long-term solution for obesity. Roux-en-Y gastric bypass, laparoscopic adjustable banding, and biliary-pancreatic diversion with duodenal switch are the most commonly described techniques.^{2,20,43} The health of these patients is of particular concern because absorption of vitamins, minerals, and drugs is altered.^{91,114,133,144,166} Pharmacokinetics of orally administered

medications may also be altered.^{133,144} Consideration of drug properties should be examined closely prior to initiation in this patient population.⁹¹

SUMMARY

- Obesity is a major health concern and a significant cause of preventable diseases and sequelae. Unproven weight loss modalities are associated with treatment failure and the potential for significant adverse events.
- Some common themes exist; combination drug therapy likely provides the best weight loss; and toxicity from proven and unproven treatments remains a significant concern.
- A balanced weight loss plan that encompasses decreased caloric intake with increased energy expenditure through exercise should be encouraged.
- Clinicians should be aware of the lack of regulation of most available diet remedies and should report adverse events involving these products to poison control centers and to the FDA MedWatch system so that appropriate regulatory actions can be taken to prevent further instances of toxicity.
- A historical review of compounds used as weight loss agents readily uncovers numerous examples of poorly conceived drug regimens, popular misunderstanding of the benefits and risk of the drugs involved, and relatively poor postmarketing surveillance leading to unnecessary morbidity and mortality.

43 ESSENTIAL OILS

Lauren Kornreich Shawn

INTRODUCTION

Essential oils are a class of volatile oils that are extracted through steam distillation or are cold pressed from the leaves, flowers, bark, wood, fruit, or peel of a single parent plant. The term essential refers to the essence of a plant, rather than an indispensable component of the oil or a vital biologic function. These organic compounds are a mixture of complex hydrocarbons that give the oil its aroma, therapeutic properties, and occasionally cause toxicity. More than 500 essential oils exist and can be categorized into five chemical groups: terpenes, quinines, substituted benzenes, aromatic/aliphatic esters, and phenols and aromatic/aliphatic alcohols.

HISTORY AND EPIDEMIOLOGY

The potential for toxicity arises from several aspects of oil production, use, and regulation. These oils are not under the US Food and Drug Administration (FDA) regulation; therefore, they may not contain the specific ingredient intended for use or may contain excessive amounts of the active ingredient, other chemicals, or various adulterants. Furthermore, there is no standardized nomenclature for many of these herbs or for the exact chemical composition of specific oil. Even with the strictest production guidelines, oils can vary by the environment the plant was grown in and by part of the plant primarily used in production. Sometimes these differences are utilized to confer a particular property to the oil in terms of aroma or believed therapeutic benefit.

Therapeutic use of essential oils can be traced back thousands of years in history to the ancient Greeks and ancient Egyptians, and it is also described in biblical writings. The first documents detailing an actual distillation process date back to the ninth century, when such oils were imported into Europe from the Middle East.¹⁵⁸ By the 16th century, concepts of separating fatty oils and essential oils from aromatic water became more defined, and oils were used frequently for fragrance, flavoring, and medicinal purposes. By the 19th century, these processes became industrialized, and specific chemicals could be identified and mass produced. Essential oils fell out of favor in the early 20th century, as new medications and a desire for modernization developed. However, in the past 30 years, resurgence in interest and use of essential oils developed as many people deemed natural products to be safer and more environmentally friendly. This chapter highlights some of the most commonly used oils for medicinal purposes that also have the greatest potential for toxicity.

Absinthe

Thujone

History. *Artemisia absinthium* is more commonly known as wormwood because of its use as an anthelmintic in ancient times. It is a member of the Compositae family, which also includes ragweed, chrysanthemums, marigolds, and daisies.¹³⁹ Absinthe is a liqueur composed of ethanol, oil of wormwood, and various other herbs, and it is known for its green color and bitter taste. It became a favorite among the artists and poets of Paris during the city's Belle Époque in the 19th century. Bohemian society enjoyed the drink by pouring water on top of a sugar cube that was suspended over a glass of absinthe. The addition of sugar water not only made the drink more palatable but also enhanced the herbal aroma and green coloration, which was referred to as the "louche effect."¹⁰¹ This ritual was commonly performed in the early evening and

thus the “green hour” was akin to a Parisian “happy hour.”¹⁰

The earliest recorded use of wormwood is found in the Ebers papyrus, which covers writing from 3550 to 1550 B.C. in Egypt.¹⁰ During the first century A.D., Pliny described wormwood’s anthelmintic properties in *Historia Naturalis*. Dioscorides’ *De Materia Medica*, which was considered an authoritative medical text through the Middle Ages, described wormwood’s ability not only to treat intestinal worms but to repel fleas and other pests with topical application.¹⁰ For millennia, wine was commonly fortified with wormwood, and the formulation is still known today, albeit in much more dilute concentrations, as vermouth (derived from the German word for wormwood, Wermut).¹¹⁷

Absinthe was first distilled in Switzerland but came to prominence during the early 19th century, with Pernod’s distillery in France.¹⁰¹ During the French-Algerian wars of the 19th century, absinthe was used medicinally by the French troops to ward off infection and prevent dysentery.¹⁰⁰ Subsequently, the returning troops introduced the drink to French society. As early as 1850, descriptions of toxicity were documented. By the 1910s, many countries had made it illegal. In the 20th century, thujone was discovered to be the toxic component of absinthe. Absinthe is still available as Pernod, a formulation that is free of thujone. However, thujone-containing absinthe, as well as recipes for making it at home, can be obtained over the Internet.

Pharmacology. The bitter taste and anthelmintic properties come from the lactones absinthin and anabsinthin.¹³⁹ However, the toxicity of wormwood is due to its thujone content. Thujone is a monoterpene ketone, which exists in α - and β -diastereoisomeric forms. Oil of wormwood may contain up to 70% thujone (α - and β -thujone).¹³⁹ The amount of the β isomer often exceeds that of α -thujone but is less toxic.⁸¹ After oral absorption, both isomers undergo species specific hydroxylation reactions by the cytochrome (CYP) P450 system and are subsequently glucuronidated and renally eliminated.⁸⁰ α -Thujone is metabolized primarily to 7-hydroxy α -thujone by CYP3A4 in humans, but there are at least six other metabolites, some of which are more prominent in other animal models.⁸⁰ The 7-hydroxy metabolite achieves a higher concentration in the brain, but it is less potent in binding the GABA_A receptor and is less toxic compared to its parent compound.⁸¹

Pathophysiology. α -Thujone is generally accepted to be the more toxic of the two isomers and is a noncompetitive GABA_A receptor antagonist, similar to picrotoxin.⁸¹ This antagonism causes neuroexcitation, which may result as hallucinations or seizures in a dose-dependent fashion. Ethanol enhances GABA activity and may have a protective effect by reducing seizures in mice.⁸¹ In the 1970s, it was speculated that thujone mediated the psychotropic effects of absinthe via cannabinoid receptors. However, further research demonstrated that despite low affinity for the CB1 and CB2 receptors, thujone failed to evoke any chemical signaling from that binding.¹¹² Currently, research suggests that the psychotropic effects may be mediated by α -thujone’s ability to desensitize the 5-HT₃ receptor.⁴⁵

Thujones induce the synthesis of 5-aminolevulinic acid synthetase, leading to increased porphyrin production.¹⁸ Individuals with defects in heme synthesis may develop porphyrialike symptoms upon ingestion of thujones. Some have speculated that Vincent Van Gogh suffered from porphyria secondary to ingestion of absinthe and other volatile oils.

Clinical Features. Clinical features of acute toxicity are similar to those of ethanol intoxication, including euphoria and confusion, which may progress to restlessness, visual hallucinations, and delirium. Seizures have also occurred. Studies in 19th-century France revealed that the oil of wormwood component in absinthe, rather than the ethanol or other aromatic herbs, was responsible for auditory and visual hallucinations and seizures in humans and dogs.^{4,12} Absinthism was recognized as a distinct disease from alcoholism as early as 1850s. It was characterized by delirium, hallucinations, tremors, and seizures. Although thujone is the purported xenobiotic in the development of these symptoms, the patients also drank excessive amounts of ethanol, so differentiating this syndrome from chronic sequelae of alcoholism is difficult.⁴

Rhabdomyolysis and acute kidney injury (AKI) have occurred following ingestion of oil of wormwood intended for preparation as absinthe.¹⁵⁹ The etiology of the rhabdomyolysis has not been elucidated.

Camphor

History. Originally derived from the bark of the camphor tree (*Cinnamomum camphora*), camphor has been widely used for centuries. It was described in writings from Marco Polo’s visits to China, and in the 16th century it was referred to as the “balsam of disease.”¹¹ Camphor has been used as an abortifacient, a contraceptive, a cold remedy, an aphrodisiac, an antiaphrodisiac, a lactation suppressor, and an antiseptic.^{9,69} In the late 19th and early 20th centuries, it was also regarded

as a cardiac stimulant and used extensively to treat congestive heart failure and cardiovascular compromise during influenza outbreaks.^{49,64,67,107,110} By the 1920s, studies demonstrated that camphor was not an effective cardiovascular stimulant, and its use began to fall out of favor.¹¹⁰ In the 20th century, camphor was predominantly used as a topical rubefacient to provide local analgesia and antipruritic effects. It also became a key ingredient in paregoric (camphorated tincture of opium), a common household remedy for diarrhea and cough used until 1970. Throughout the 20th century, camphor was also available as a nonprescription remedy in the forms of camphorated oil, which was 20% camphor in cottonseed oil, and spirits of camphor, which was 10% camphor in alcohol. Consequential toxicity occurred in cases where camphorated oil was mistaken for castor oil and ingested in large amounts.^{12,32,152} In 1982, the FDA limited any product from containing more than 11% camphor as well as placed an outright ban on camphorated oil after numerous reports of significant morbidity and mortality. Today camphor can be found in topical products such as Vick's Vapo-Rub and Tiger Balm. It was also used extensively as a moth repellent. Despite restrictions on its sale by the FDA, concentrated camphor products are still found in the United States. They are illegally sold in various immigrant communities for use as pesticides and medicinal remedies.⁹²

Pharmacology. Camphor is a bicyclic monoterpene ketone that is rapidly absorbed from the gastrointestinal (GI) tract. Serum concentrations can be detected within 15 minutes of ingestion.^{121,125} It is also readily absorbed from the skin and mucous membranes.⁹² It also has been documented to cross the placenta and blood–brain barrier.¹²⁵ A detectable concentration was found in amniotic fluid 20 hours after maternal ingestion.¹²⁵ Camphor is very lipophilic with a large volume of distribution. It is metabolized in the liver by CYP2A6 to 5-exo-hydroxycamphor, but other studies using animal models have cited 5-endo-hydroxycamphor and 3-hydroxycamphor as significant metabolites.^{71,128,152} These metabolites then undergo glucuronidation and are excreted in the urine.¹²⁸

Pathophysiology. The mechanism for seizure activity is still unknown. Camphor desensitizes the transient receptor potential vanilloid subtype 1 (TRPV1) channel, a nonspecific cation channel that mediates thermosensation and nociception in the peripheral nervous system (Fig. 43–1).¹⁶⁴ Similar to other topical analgesics with effects on these channels, it is postulated that desensitization mediates the analgesic and cooling effect of topical camphor products. There are TRPV1 receptors found in the central nervous system (CNS), but it is unknown whether they are implicated in the CNS effect of camphor toxicity. Autopsies of case reports and animal studies have shown neuronal necrosis and degeneration on pathology, but the mechanism of action remains elusive.¹⁴¹

FIGURE 43–1. The transient receptor potential vanilloid subtype 1 (TRPV1) receptor is a nonspecific cation channel that

is located on the skin and bladder, in the peripheral nociceptors and the dorsal horn of the spinal cord, and in the airway. Stimulation by heat, acidemia, and inflammation increases its activity, whereas camphor, capsaicin, and resiniferatoxin are direct agonists. Once open, TRPV1 stimulates intracellular signaling via PIP_2 to relay sensation of burning pain, noxious heat, airway tightness, and micturition.

Hepatotoxicity is also reported and can range from a mild elevation in aminotransferase concentrations to fulminant hepatic failure. Children seem to be more susceptible to hepatotoxicity since they have relatively immature liver enzymes and glucuronidation systems. The hepatotoxicity may present similarly to Reye syndrome but does not have the same characteristic findings on biopsy.⁸⁷

Clinical Features. Camphor toxicity is reported after nasal, topical, inhalational, and oral administration.^{32,88,121,137,147,155} Toxicity has developed within 5 to 90 minutes after ingestion.¹² Case reports of delayed onset of symptoms are complicated by unknown time of ingestion or concomitant illness.¹⁰⁹ In a retrospective review of 182 cases, no patient developed symptoms more than 6 hours after ingestion.⁶⁹ The ingestion of 2 g has caused significant toxicity in adults and as little as 0.7 to 1 g of 20% camphorated oil (1 teaspoon) has been fatal in children.^{32,141} Other reports describe children having seizures but surviving after ingesting 0.5 to 6 g of camphor.¹³⁴

Generally, the first symptoms are related to GI irritation and include nausea and vomiting, although patients who were exposed via topical or inhalational administration rarely suffer from GI symptoms. Patients have complained of feeling warm, faint, and vertiginous as well as headaches.⁸⁸ Severe symptoms include confusion, agitation, delirium, and hallucinations.^{20,29,49,147} Seizures are common and usually develop within minutes to a few hours of exposure.¹³⁴ Status epilepticus is reported.^{39,92}

Clove Oil

Eugenol

History. Clove oil is extracted from the plant *Syzygium aromaticum*, also known as *Eugenia aromatica*. This evergreen plant is native to the Maluku islands of Indonesia (traditionally known as the Spice Islands). Its dried, unopened buds are known as cloves, a descriptive name derived from the Latin word *clavus*, meaning nail. During the Chinese Han dynasty, subjects were required to chew cloves in order to mask bad breath when appearing before the emperor. In medieval and Renaissance Europe, cloves were considered to be a valuable commodity. They were used for flavoring and fragrance, as well as for medicinal purposes, and that tradition remains intact today. The first recorded medicinal use of cloves in Western society can be found in *The Practice of Physic*, which was written in French in the 1640s and translated into English in 1687.³⁷ Clove oil is commonly mixed with zinc oxide as a sealant in dentistry, a practice that has been described as far back as 1873.⁸³ Clove oil is still used to alleviate toothaches, and one study found it just as effective as topical benzocaine for analgesia.³

Pharmacology. Typically, clove oil contains 60% to 90% eugenol, which is the primary active component. Eugenol undergoes sulfonation and glucuronidation in the liver, with a minor pathway involving the CYP450 system to form a reactive intermediate that requires glutathione for proper elimination.¹⁴⁹

Pathophysiology. The anesthetic properties of eugenol are mediated by blockade of various ion currents in nerves. This was initially demonstrated by the ability to block conduction of action potentials in frog sciatic nerves.⁹⁷ Given the structural similarity to capsaicin, studies sought to determine if the effects were mediated by a common mechanism. Studies of rat dorsal root ganglion cells suggest that eugenol acts in both a capsaicin receptor mediated pathway and by an independent pathway.¹¹⁵ Capsaicin requires the TRPV1 receptor to inhibit voltage-gated calcium channels in order to desensitize peripheral nociceptors, but eugenol does not (Fig. 43–1).^{103,114} Eugenol also inhibits voltage-gated sodium channels independently of TRPV1, and this likely mediates its anesthetic effects.¹¹⁸ Eugenol similarly can block voltage-gated potassium channels in neurons, which suggests a possible mechanism for the irritating effects of eugenol as potassium efflux is required to terminate action potentials and neurotransmitter release.¹⁰⁵

Studies with rat hepatocytes demonstrated that eugenol can cause glutathione depletion and subsequent hepatotoxicity in

a dose- and time-dependent manner. The loss of glutathione occurred prior to the onset of cell death in these studies.¹⁵⁰ Furthermore, N-acetylcysteine (NAC) was able to prevent glutathione depletion and cell death.

Eugenol inhibits prostaglandin synthetase, which may support its claims as an antiinflammatory agent in dentistry.⁸³

Clinical Features. There are several reports of allergic reactions and local irritation when eugenol zinc oxide was used for dental procedures.^{14,98,132} There are fewer case reports of systemic toxicity from other forms of exposure. However, in case reports of infants and children ingesting clove oil, depressed mental status, anion gap metabolic acidosis, and hepatotoxicity complicated by coagulopathy and hypoglycemia is reported.^{22,56,75,86,102}

A single case report described a 24 year-old woman who developed permanent infraorbital anesthesia and anhidrosis after spilling a small amount of clove oil on her face in an attempt to relieve a toothache.⁸⁴

Acute respiratory distress syndrome is reported with intravenous administration of clove oil. Similar findings of perivascular, interstitial, and alveolar edema are found in animal studies. The proposed mechanism is oxidant mediated, but this has not been verified.^{93,162}

Eucalyptus Oil

Eucalyptol

History. Oil of eucalyptus is derived primarily from *Eucalyptus globulus*, a tree native to Australia. Eighteenth-century British explorers noted that the aboriginal people traditionally used eucalyptus as a fever remedy, so they brought it to England for further examination. The introduction of eucalyptus oil to the West led to an increased demand, because it was increasingly used to treat the symptoms of the common cold and influenza. The oil was believed to be so effective that there were public campaigns to grow the trees in areas of Europe stricken with malaria and other infectious diseases. Great effort was made to determine how best to cultivate these plants in the colder, damper European environment.^{6,126} In the 19th and early 20th centuries, eucalyptus oil was a common household remedy for coughs and fevers, and it was also used as an antiseptic.³⁶ It was even reported as effective in treating hemorrhage, burns, and diabetes.^{7,140,151}

Pharmacology. Eucalyptus oil contains almost 70% eucalyptol, a monoterpene cyclic ether also known as 1,8-cineole. It is rapidly absorbed from the GI tract and metabolized by the 3A family of CYP enzymes, particularly 3A4 and 3A5.⁵⁰ In rats, the main urinary metabolites are 2-hydroxycineole, 3-hydroxycineole, and 1,8-dihydroxycineol-9-oic acids.^{50,108} In humans, only the 2-hydroxy and 3-hydroxy metabolites are found.⁵⁰

Pathophysiology. The effect of eucalyptus on upper respiratory symptoms may be due to a myorelaxant effect as potassium-induced contractions of airway smooth muscle are inhibited.¹⁰⁶ However, it also potentiates acetylcholine-induced contractions of the trachea in vitro, possibly by inhibiting acetylcholinesterase.¹⁰⁶ Some authors have hypothesized that this mediates the upper respiratory irritation that commonly plagues workers who process eucalyptus trees for papers and other materials. Eucalyptol inhibits monocytes from producing several cytokines, particularly tumor necrosis factor (TNF)- α and interleukin (IL)-1 β , from being produced.⁹⁰ It also suppresses arachidonic acid metabolism. Some hypothesize that this makes eucalyptol effective at controlling mucous hypersecretion and a potential adjunct in controlling asthma and chronic obstructive pulmonary disease, for which it is commonly used as an alternative medicine.^{89,90,161}

The mechanism of toxicity has yet to be elucidated. Some research suggests that eucalyptol may affect the autonomic nervous system.⁵⁷ Animal studies have proven to be difficult to interpret as mice seem relative insensitive to the oil and other animals require extremely high amounts to achieve toxic effect.⁴³ Significant morbidity and mortality are rare.

Clinical Features. Typical symptoms include drowsiness, slurred speech, ataxia, nausea, and vomiting.^{58,143} Rarely, seizures and coma can occur.⁷⁰ Symptom onset is usually within minutes to hours and rarely exceeds 4 hours. In children, significant toxicity has been reported after ingesting as little as a teaspoon. Fatalities have been reported in adults who have ingested as little as 4 mL, but a patient survived a 120- to 200-mL ingestion after receiving mannitol infusions and dialysis.^{58,70} Inhalational and dermal exposures seem to have minimal toxicity as long as the patient is promptly removed or

decontaminated from the exposure.¹⁴³

Lavender

History. Lavender is one of the most commonly used essential oils for fragrance and aromatherapy.²⁸ It was used by the ancient Romans and Greeks for its believed antimicrobial, carminative, sedative, and antidepressive properties. The oil is produced by steam distillation of the flower heads and foliage of the *Lavandula* species. However, the chemical composition and fragrance of the oil is determined by the proportion of flowers distilled within a particular batch.

There are four commonly used lavenders: *Lavandula latifolia*, a Mediterranean variety; *Lavandula angustifolia*, commonly known as English lavender (or *L. officinalis*); *Lavandula stoechas*, commonly known as French lavender; and *Lavandula x intermedia*, which is a sterile cross between *L. latifolia* and *L. angustifolia*.²⁸ The lavenders generally have the same major chemical constituents in their oils and ethnobotanical history, but some species have specific therapeutic benefits ascribed to them. For example, *L. stoechas* was traditionally used as a headache remedy, *L. latifolia* as an abortifacient, and *L. angustifolia* as a diuretic.²⁸ However, many of these effects, regardless of species used, have never been substantiated in the medical and scientific literature. Lavender oil is most commonly used in aromatherapy to enhance mood, decrease anxiety, or control pain. Most studies demonstrating improved pain control, decreased anxiety, or improved mood were small studies or poorly controlled.

Pharmacology. The main components of lavender oil contains linalool, linalyl acetate, 1,8-cineole, β -ocimene, terpinen-4-ol, and camphor.²⁸ The proportion of each within a given batch of oil may depend on the plant used and type of distillation. Plants with smaller camphor components, such as *L. angustifolia*, are used more for fragrance and cosmetic purposes because their aroma is considered to be more pleasant. Plants with higher camphor content have been traditionally used for insect repellent and antimicrobial uses.

Linalool and linalyl acetate are the components believed to be responsible for the neuropsychiatric effects of lavender oil, specifically sedative and narcotic effects. These compounds are rapidly absorbed through the skin and can reach peak serum concentrations as soon as 19 minutes postexposure.^{28,85} Linalool inhibits both nicotinic receptor-mediated acetylcholine release and glutamate release.^{122,135}

L. angustifolia has activity against methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus faecalis* as well as other bacteria.¹⁶³ Its potential as an antimicrobial and preservative in cosmetics is demonstrated.⁹⁹

Pathophysiology. Lavender oil is very allergenic. Linalool is not electrophilic or chemically reactive, suggesting it would not be a contact allergen.⁷² Linalyl acetate has an electrophilic center and is a weak allergen in studies.¹³⁸ However, both of these compounds immediately oxidize when exposed to air, generating hydroperoxides, which are strong allergens. This oxidation occurs regardless of whether pure linalool, linalyl acetate, or lavender oil is used.^{72,138}

A case series reported the development of gynecomastia in three prepubertal boys using lavender oil.⁷⁸ All three children had extensive endocrine evaluations, with no abnormalities detected, and in each case the gynecomastia resolved when lavender oil was discontinued. In vitro data showed that lavender oil elicits a dose-dependent increase in estrogen responsivity and antiandrogenic activity in breast cancer cell cultures, similar to the effects of estradiol.⁷⁸

Clinical Features. The predominant clinical feature of exposure is contact dermatitis. Unexplained or “idiopathic” gynecomastia in prepubertal boys with negative endocrine evaluations should prompt questions regarding the use of these essential oils.

Nutmeg

Myristicin

History. Nutmeg and mace originate from the evergreen tree *Myristica fragrans*, which is native to the Maluku islands of Indonesia (Spice Islands) and was imported to Europe as early as the mid-12th century.^{59,136} However, today, nutmeg is more commonly imported to the United States from Malaysia, Grenada, Trinidad and other parts of the Caribbean.¹³⁶ The name nutmeg refers to the seed of the tree, which looks like a glossy brown nut. Mace is derived from the scarlet-colored aril that encloses the seed.

Although nutmeg is a common household spice and flavoring agent, it has been used for centuries for various ailments, including digestive disorders, cholera, rheumatic disease, psychiatric disorders, and pain.⁵⁹ Mace has been used as an aphrodisiac, but nutmeg has been commonly used in Europe and North America, albeit ineffectually, as an emmenagogue and abortifacient.¹²³ Indeed, most of the cases of nutmeg poisoning in the early 20th century were due to women attempting to terminate pregnancies or induce menses.⁶⁸ However, most cases of toxicity today are due to people using nutmeg as a natural high.^{1,27,120,131} The first reported case of nutmeg poisoning is attributed to Lobel, who described delirium in a pregnant woman who ingested 10 or 12 nutmeg seeds in 1576.²⁷ In 1832, the famous scientist Purkinje demonstrated the toxicity of nutmeg by ingesting seeds, causing delirium and then stupor.⁶⁸

Pharmacology. The nutmeg seed yields 7% to 16% volatile oil, 4% to 8% of which is myristicin.⁷³ Myristicin is believed to be the psychoactive component of the oil, but some studies have brought that into question. It was initially hypothesized that myristicin was metabolized to the amphetamine derivative 3,4-methylenedioxy-5-methoxyamphetamine (MMDA) by the addition of ammonia to the allyl side chain. Elemicin, another main ingredient of the volatile oil, would be metabolized to 3,4,5-trimethoxyamphetamine (TMA).¹³³ This was further supported by detection of MMDA by thin layer chromatography of rat liver incubated with myristicin.²⁰ However, in vivo studies could neither replicate these results nor find evidence of the amphetamine derivatives. Gas chromatography of urine from rats and humans exposed to nutmeg, pure myristicin, or elemicin did not detect MMDA, TMA, or evidence of the original compounds.¹⁷ However, other metabolites were found, suggesting extensive liver metabolism. It was later determined that CYP3A4 and CYP1A2 were primarily involved in the formation of myristicin's main metabolite, 5-allyl-1-methoxy-2,3-dihydroxybenzene.¹⁶⁶

Pathophysiology. Studies in mice suggested that nutmeg and fresh myristicin are monoamine oxidase inhibitors but that excessive doses could reverse that effect,¹⁵⁴ and nutmeg was shown to be not as potent as known monoamine oxidase inhibitors on the market at the time. In the 1960s, nutmeg was studied as a possible antidepressant in five patients with mixed results, but a formal trial of nutmeg as a psychiatric medication was never conducted.¹⁵⁴

Animal data show that nutmeg can induce tachycardia and increase the speed of conduction through the atrioventricular node in the acute setting, but chronic exposure caused bradycardia.¹³⁰ The exact mechanism for this is unknown.

Cats appear to be exquisitely sensitive to nutmeg and develop not only acute mental status changes with nutmeg exposure but liver damage leading to hepatic encephalopathy.¹⁵³ This has not been reported in humans.

Clinical Features. Tachycardia, nausea, and dry mouth are common in acute exposures. Some patients develop GI distress and vomiting. CNS symptoms can range from giddiness to a sense of detachment or impending doom to hallucinations and delusions.^{1,8,38,68,120} Nutmeg ingestion rarely causes significant morbidity or mortality. Only two deaths have been reported. In 1887, an 8 year-old boy became comatose after ingesting two nutmegs and died the next day; however, he also received a wide variety of analeptics that may have been more harmful than the initial exposure.²⁷ The other case involved a detectable serum myristicin concentration on autopsy of a 55 year-old woman who had a toxic serum concentration of flunitrazepam and whose stomach contents smelled strongly of nutmeg.¹⁴⁴ It is unclear if the nutmeg contributed to her death.

Pennyroyal

History. Oil of pennyroyal is derived from the plant *Mentha pulegium* from the Labiatae family. It has a mintlike odor and is still used as a flavoring and fragrance agent in foods and cosmetics. Its initial use was as a flea repellant. Pulegium is derived from the word *pulex*, which is Latin for flea.⁶⁶ Pennyroyal has been used for centuries as an emmenagogue and abortifacient, and most reported toxicity has resulted from women ingesting large quantities to induce these effects. Dioscorides listed pennyroyal as an abortifacient in his *Da Materia Medica*, and the Greek playwright Aristophanes made frequent reference to it in his plays.¹²⁴ Women still use pennyroyal for these purposes today.

Pharmacology. The primary active ingredient in pennyroyal is pulegone, a monoterpene. In particular, R(+)-pulegone is the active isomer.⁶⁵ Pulegone is metabolized by the CYP450 system into several metabolites, including menthofuran, which

is thought to be the metabolite primarily responsible for hepatotoxicity, although other reactive intermediates are also implicated.^{66,148}

Pathophysiology. In animal studies, pennyroyal causes centrilobular hepatic necrosis.⁶⁵ In a rat model, pulegone depletes glutathione in hepatocytes and in the plasma. Furthermore, hepatotoxicity is significantly increased in glutathione-depleted animals. However, another unknown reactive metabolite has been implicated because blocking the CYP450 system prevents glutathione depletion. Menthofuran had a minimal effect on glutathione concentrations in the plasma and liver, and its ability to cause hepatotoxicity was not affected by glutathione depletion, suggesting a role on another reactive metabolite.¹⁴⁸ R(+)-pulegone also causes necrosis in lung epithelium, but the mechanism remains unknown.⁶⁵

Recently, R(+)-pulegone has been shown to decrease inward current from L type calcium channels as well as block the inward rectifying potassium channels on the rat myocardium.⁴²

Clinical Features. Common initial signs and symptoms are nausea, abdominal pain, and vomiting, often occurring within a few hours of exposure.⁵ CNS toxicity, including seizures and coma, can develop in severe cases.^{19,51} Ingestion of as little as 5 mL has been implicated in severe CNS toxicity. However, in most cases, ingestion of 10 mL is primarily associated with GI symptoms and mild CNS symptoms such as dizziness and lethargy. Fatal cases involving liver failure, kidney failure, and disseminated intravascular coagulation have occurred with ingestion of 15 mL, but these often involve large amounts or multiple doses over a short period of time.^{2,146,156} In reported cases, patients either ingested a tea brewed from the leaves of *M. pulegium*, a tablet containing the herb, oil of pennyroyal, or essence of pennyroyal, which is an alcoholic preparation.^{19,31,51,63} Most cases of severe toxicity involved women ingesting large amounts of the herb in order to induce an abortion; however, two cases involved confusing the leaves of *M. pulegium* for nontoxic mint leaves to make tea.¹³

Peppermint Oil (Menthol)

History. Menthol or peppermint oil is one of the most commonly used flavoring agents in the world. It is derived from the distillation of leaves of the *Mentha piperita* herb, which is native to Europe and parts of Asia but easily grows in North America as well.¹¹¹ Before World War II, menthol was primarily exported from China and Japan, but as those trade routes became disrupted during and after the war, Brazil became the predominate exporter.⁵² Peppermint flavor is common in oral care products, candies, cosmetics, pharmaceuticals, and beverages. Pure crystalline menthol was extracted from plants and introduced as a medicine in the 19th century. In the late 19th century, its use in upper respiratory illness was described, but the author cautioned that more information was needed to “become familiar with its actions and know its limitations.”⁵³ However, menthol is still used today for many remedies with little supporting data. It is sold as an herbal remedy for pruritus, GI disorders such as irritable bowel syndrome, cough and cold symptoms, as well as a topical analgesic.¹⁶⁵ Pure distilled peppermint oil is more expensive and primarily produced by the United States for toothpaste and other dental care products. Corn mint oil, also known for its minty scent and flavor, is derived from *Mentha arvensis* and can contain 70% to 80% menthol. However, menthol derived from this plant has a more herbaceous flavor and is less commonly used commercially.⁵²

Pharmacology. There are four pairs of optical isomers that exist for menthol given its three asymmetric carbons on the central ring of the structure. However, only the –/– menthol form is found in nature and is the most potent.⁵² Peppermint oil typically contains 30% to 55% menthol.⁷⁶

Menthol is very lipid soluble and easily absorbed through the skin. Menthol is rapidly metabolized by the CYP450 system to primarily to p-menthane-3,8 diol and then glucuronidated and eliminated in the urine.⁵² Menthol is a moderate inhibitor of CYP3A4, but its effects on the metabolism of other drugs such as the dihydropyridine calcium channel blockers are not clear.⁴⁸ In human pharmacokinetic studies, only glucuronidated menthol is detected in urine in ranges of 45% to 46% of the menthol ingested.⁶¹ The plasma half-life of menthol glucuronide was determined to be 56.2 minutes and 42.6 minutes, respectively, when mint teas and candies were used.⁶¹

Pathophysiology. In the late 19th century, Goldscheider hypothesized that the cooling effects of menthol involved stimulation of a thermoreceptor. Two independent studies demonstrated the transient receptor potential cation channel subfamily M member 8 (TRPM8) is activated by both menthol and thermal stimuli in the cool to cold range of 46° to 82°F (8°–28°C) (Fig. 43–2).¹¹⁹ TRPM8 is a member of the transient receptor potential family of excitatory ion channels (the same receptor family as TRPV1).¹⁵ Menthol and cold stimuli increase intracellular calcium, which leads to depolarization and generation of an action potential. Currently, there are six known transient receptors that perceive temperatures ranging from noxious heat to noxious cold, depending on the type or combination of receptors activated (Fig. 43–2).^{119,157} These receptors are primarily expressed by small-diameter sensory neurons of the dorsal root ganglion and trigeminal nerves.¹⁵ Some data suggest that menthol’s analgesic properties are mediated by its effects on sodium channels.⁶⁰

FIGURE 43–2. Schematic of the six known mammalian thermo-TRP channels based on their temperature threshold for activation. Certain natural substances can activate these receptors, which may lead to burning or noxious heat sensation.

Menthol has been investigated as an adjunct to irritable bowel syndrome therapy. In vitro data with isolated animal ileum and jejunum tissue show that menthol reduces contractions by reducing calcium influx, even when such tissue was exposed to acetylcholine, histamine, and serotonin.⁷⁹ In some countries, menthol is sold in an acid resistant preparation as a carminative for irritable bowel symptoms. Menthol and peppermint oil both inhibit 5-HT₃ receptors in vitro as well as reduce serotonin-induced contractions of rat ileum, which could mediate some of the antiemetic effects.⁷⁶

Menthol is commonly used to relieve the symptoms of upper respiratory infections, in particular rhinitis. However, studies have shown that despite the sensation of improved airflow and decreased congestion, menthol actually causes increased nasal congestion.^{53,54} Inhalation of menthol, camphor, or eucalyptus did not decrease nasal resistance to airflow, despite the fact that all of the subjects reported an increased sensation of airflow.²⁴ Similar results were found for nasal menthol lozenges.⁵⁵

Clinical Features. Application of menthol to skin or mucosa causes the sensation of coolness or warmth. Case reports regarding menthol toxicity are rare. One report pertains to Olbas oil, which contains 35% menthol. However, it also contains 35% eucalyptus oil, as well as other oils in smaller amounts. In this report, the child developed ataxia, nystagmus, and altered mental status.¹¹⁶

Pine Oil

History. Pine oil is commonly used as a household cleaner, varnish, and polish. In the past, it had medicinal uses as an expectorant and topical liniment. Turpentine is an oleoresin solvent—a mixture of pine oils and resins distilled from the tree genus *Pinus*. Pine oil is also distilled from the same trees but does not include any resins. Turpentine is used as a degreaser and paint thinner. Pine oil is commonly found in Pine-Sol and similar household cleaners. These cleaners typically include 20% pine oil, 6% to 10% isopropyl alcohol, and other hydrocarbons.

Pharmacology. The lethal dose is in the range of 60 to 120 g in adults.⁹⁶ The major terpene is 1- α -terpineol. The major metabolite is bornyl acetate, which is produced by the enzymatic processes of hydration, hydroxylation, rearrangement, acetylation, and reduction in the liver.⁹⁶ The metabolites are excreted through the kidneys and by exhalation. Pine oil is readily absorbed, and clinical effects usually occur within 2 to 3 hours postingestion.⁹¹

Pathophysiology. Pine oil and turpentine are volatile hydrocarbon compounds with low viscosity. Aspiration and inhalational injury is common when low-viscosity hydrocarbons are ingested or inhaled (Chap. 108). Animals injected with pine oil develop acute respiratory distress syndrome (ARDS), but the mechanism is unknown.¹⁴²

Clinical Features. The most common reported symptoms are impaired mentation, psychomotor agitation, delirium, headache, nausea, ataxia, and GI distress. GI irritation and gastritis are reported, but actual perforation or high-grade lesions have not been found.³³ Acute kidney injury is also reported.⁹⁶ An isolated case report of hemorrhagic cystitis occurring after a patient ingested turpentine for several days to treat a cold is described.⁹⁴ Fatalities are rare, but are more likely to occur when the patient is elderly.¹⁶⁰ The most severe outcomes involve an aspiration pneumonitis that can develop into ARDS or a secondary pneumonia.^{21,91}

Tea Tree Oil

History. Tea tree oil is derived from the distillation of leaves of *Melaleuca alternifolia*, a plant that is native to Australia. The *Melaleuca* genus belongs to the Myrtaceae family and contains more than 230 species. The international standard for tea tree oil does not specify which *Melaleuca* species must be used but rather dictates a certain chemical content.²⁵ Traditionally, *M. alternifolia* has been the primary source for the oil. Nevertheless, synonyms and ambiguous naming of various oils and plants make it difficult to identify the primary plant product. Tea tree oil is also known as melaleuca oil or ti tree oil in many cases. Furthermore, ti tree is the Maori and Samoan common name for plants of the *Cordyline* genus, a completely different plant.²⁵ There are oils from other *Melaleuca* species on the market that possess different chemical properties from that of tea tree oil, further complicating matters. Tea trees can also be known as paperbark trees, but paperbark oil may refer to oil from another type *Melaleuca* tree or even a nonrelated tree such as *Leptospermum* species.

The first reported use of *M. alternifolia* was in Australian Aborigines. Crushed leaves were inhaled to treat coughs and cold symptoms, and poultices of the leaves were applied to wounds. Oral histories describe swimming or bathing in healing lakes composed of decaying fallen tea tree leaves as a treatment for a variety of ailments.²⁵ The oil itself was not distilled until the 20th century, at which time it was touted as an antibacterial agent. Commercial production began after medicinal properties of the oil were first reported in the 1920s. Production slowed after World War II, presumably because of the increased use of antibiotics and decreased desire to use natural products. Renewed interest in the oil began in the 1970s, and production increased as well as became more standardized.

Pharmacology. Data on safety and toxicity are scant. Pharmacokinetic and pharmacodynamic data are even more lacking. Animal studies and case reports of human poisoning demonstrate toxicity with oral exposure. The LD₅₀ for rats is 1.9 to 2.6 mL/kg, and rats dosed with less than 1.5 mL/kg appeared lethargic and ataxic.²⁵

Tea tree oil is comprised of terpene hydrocarbons and contains more than 100 components.²⁵ There can be variability in the composition of oils sold on the market, but there is an international standard stipulating that tea tree oil should contain at least 30% terpinen-4-ol, which is believed to be the primary antimicrobial agent and less than 15% 1,8-cineole, which is believed to be primarily responsible for the irritating properties.²⁵ There are other hydrocarbons found in tea tree oil that

help make up its specific chemotype for the standard, but are less involved in the presumed medicinal properties.

Pathophysiology. Tea tree oil is predominately used as a topical antiseptic, and its antimicrobial effects have been the most studied use of the oil. Studies show that it is bactericidal, and its mechanism of action has been partly elucidated. Tea tree oil, as a lipophilic hydrocarbon, has been found to disrupt the membranes of liposome model systems, supporting the hypothesis that it kills bacteria by disrupting their cell membranes.³⁵ Tea tree oil does not cause bacteria to lyse per se but makes them more susceptible to lysis when exposed to hypertonic medium, or at least it causes an inability to recover from leakage of intracellular contents over time. This is demonstrated by leakage of potassium ions and 260-nm light-absorbing material (a marker of leakage of cytoplasm contents) in *S aureus* and *Escherichia coli*.^{26,34} Tea tree oil also inhibits respiration in *S aureus*.^{26,35} The hydrocarbons 1,8-cineole and terpinen-4-ol were found to be primarily responsible for this phenomena.²⁶ Although 1,8-cineole was initially thought not to play a role in the antimicrobial activity of the oil, it seems to penetrate and disrupt the cellular membranes of bacteria. Terpinen-4-ol and α -terpineol have been shown to have the greatest antimicrobial activity.

Tea tree oil also has antiinflammatory effects. Specifically, it has been shown to inhibit lipopolysaccharide-induced production of the inflammatory mediators TNF- α , IL-1 α , IL-10, and prostaglandin E₂ by monocytes in vitro.⁷⁴

Clinical Manifestations. Skin irritation and allergic reactions are common effects with topical exposure. The allergic reactions are hypothesized to occur after the oil has undergone significant oxidation.¹²⁹ The hydrocarbon 1,8-cineole has been implicated as the main irritating component, but there are little data to support this theory. In some of the cases of prepubertal gynecomastia reported in boys exposed to lavender oil, the patients were also exposed to tea tree oil.⁷⁸ However, it has not been demonstrated that tea tree oil affects the endocrine system. When ingested, tea tree oil commonly causes drowsiness, ataxia, and slurred speech. Case reports of children unintentionally ingesting a 100% concentration of tea tree oil show symptoms developing within 30 minutes of exposure. One child had resolution of symptoms within 5 hours and another had to be intubated but had improvement in neurologic symptoms within 10 hours.^{48,122} In all reported cases of pediatric and adult oral poisoning, patients have responded well to supportive care alone; no deaths have been reported.^{48,122,135}

Oil of Wintergreen

Methyl salicylate

History. Oil of wintergreen was originally derived from *Gaultheria procumbens*, or the Eastern Teaberry, which is a fragrant ground cover plant found in North America. The leaves were steamed and distilled to produce the oil that was used topically to relieve the symptoms of rheumatism. Oil of wintergreen is also obtained from the twigs of Sweet Birch, or *Betula lenta*. The active ingredient in oil of wintergreen is methyl salicylate, which has a pleasant, minty smell and taste, posing a significant hazard to children. Pure oil of wintergreen contains at least 98% methyl salicylate, but most commercial preparations of methyl salicylate contain far less.⁴⁷ FDA regulations require that any drug containing more than 5% methyl salicylate have a warning against using it other than as a topical agent and keeping it out of the reach of children.⁴⁰ Oil of wintergreen has been used as a fragrance and flavoring agent in foods and household products.⁸² It is also found in topical preparations worldwide, such as Tiger Balm and Ben-Gay, which are used to treat inflammation and myalgias. In many Asian countries, topical oils with benign, poetic names such as red flower oil and white flower oil contain high concentrations of methyl salicylate and are quite toxic when ingested.^{29,30} Further confusing consumers and practitioners, there are many other names for this essential oil, including checkerberry oil, sweet birch oil, mountain tea, teaberry, groundberry oil, gaultheria oil, and spicewood oil.⁴⁷

The first reported case of toxicity occurred in 1832, when six soldiers used the oil to flavor their tea.⁴⁶ The seminal case series was reported in the 1930s in which 43 exposures were tabulated, 20 of which involved children under the age of 4 years and had a 75% fatality rate.¹⁴⁵ The smallest lethal dose in this series was 4 mL of oil of wintergreen and 6 mL was reported to be a lethal dose in a 21 year-old man.

Pharmacology. Methyl salicylate is absorbed both from the GI tract and transdermally. Normally, only 12% to 20% of topical salicylate is absorbed from the skin after 10 hours of application.¹²⁷ Heat, inflamed or broken skin, and prolonged use of occlusive dressings can increase absorption.^{23,77,113} Children have died following topical application.²³ Children are presumed to be at greater risk for toxicity due to their higher surface area-to-weight ratio and more permeable skin. Once

absorbed, methyl salicylate enters the circulation and is transported to the liver, where it undergoes hydrolysis to form salicylic acid.⁴¹ Methyl salicylate is a carboxylic acid ester. Most of the studies of salicylate metabolism involve aspirin, which is a phenolic ester. It is assumed that all forms of salicylate have similar properties after they are converted to salicylic acid. The salicylic acid undergoes conjugation with glycine and glucuronic acid, forming salicyluric acid, salicyl acyl, and phenolic glucuronide. Salicylates then undergo renal elimination in the forms of salicyluric acid (75%), free salicylic acid (10%), salicylic phenol (10%) acyl (5%) glucuronides, and gentisic acid (<1%).^{16,41,104}

Pathophysiology. Five milliliters (one teaspoon) of oil of wintergreen is equivalent in salicylate content to 7 g of aspirin, which has been a fatal amount in some reported cases. An extensive discussion of salicylate pathophysiology is given in [Chap. 39](#).

Clinical Features. An overdose of methyl salicylate presents similarly to that of other salicylates such as aspirin. Salicylate poisoning is characterized by diaphoresis, nausea, vomiting, tinnitus, hyperpnea, and tachypnea. Mental status changes are sign of severe toxicity. Symptom onset can be within a few hours given rapid absorption of the oil. Severe toxicity is associated with seizures, cerebral edema, ARDS, coma, and death. Further details on evaluation and management can be found in [Chap. 39](#).

DIAGNOSTIC TESTING

Laboratory testing is of little utility in most essential oil toxicity, and the patient's clinical status will determine what tests are indicated. Some essential oil exposures do require specific studies, and they are listed below. Generally, blood or urine concentrations of the active ingredients are not available in a meaningful time frame and cannot and should not guide management. Patients who present with altered mental status or seizures warrant a complete evaluation that may include a rapid assessment of glucose, basic metabolic studies, a head computed tomography scan, and lumbar puncture for serious potential structural, infectious, or metabolic etiologies. In patients who present with respiratory distress, chest radiographs, and continuous pulse oximetry are warranted.

- **Absinthe:** Laboratory studies should include a complete blood count (CBC), chemistry panel, creatine phosphokinase concentration, and glucose monitoring in patients who present with seizures. Urinalysis should be performed to evaluate for myoglobinuria.
- **Pennyroyal:** CBC and liver function studies, including the aminotransferases, bilirubin, prothrombin time, and partial thromboplastin time, and a β -human chorionic gonadotropin in women are indicated, because many women ingest pennyroyal to terminate unwanted pregnancies.
- **Oil of wintergreen:** Serum salicylate concentrations, blood gas, serum potassium concentration, and urine pH should be sent every 1 to 2 hours to determine extent of toxicity and need for treatment ([Chap. 39](#)).

TREATMENT

The mainstay of treatment of symptomatic essential oil toxicity is supportive care, including monitoring of vital signs, intravenous fluids, and supplemental oxygen as needed. A dose of activated charcoal may be helpful in alert patients with an intact airway, but if there is a concern for seizures, activated charcoal may need to be withheld or deferred until the airway is protected. Dermal exposures should be properly decontaminated to prevent further absorption. Benzodiazepines are the mainstay of treatment in patients who present with agitation and seizures.

A few of the essential oils require specific treatment:

- **Absinthe:** If rhabdomyolysis is present, hydration and urinary alkalization may be appropriate, depending on the clinical severity.
- **Camphor:** Most patients need supportive care with a focus on airway and circulatory management as well as aggressive treatment of seizures. Barbiturates are frequently cited as a first-line treatment of seizures based on one animal study that demonstrated decreased neuronal damage with administration of pentobarbital.¹⁴¹ However, it is likely that appropriate use of benzodiazepines would be just as effective. Given the risk of seizures and altered mental status, inducing emesis is not recommended. There is no proof of any benefit with orogastric lavage, and the rapid absorption of camphor from the GI tract decreases its likelihood of utility. The molecular weight and lipophilic nature of camphor indicates that it would likely be absorbed by activated charcoal. One animal study that underdosed the amount of activated charcoal as well as gave subtoxic doses of camphor indicated that activated charcoal was not effective.⁴⁴ There have been no further studies examining this issue; however, given the risk of aspiration from emesis and seizure, activated charcoal should only be considered in patients with massive life-threatening ingestions and protected airways. There have been case reports of improvement in mental status and seizures with lipid dialysis (using soybean oil) as well as hemoperfusion with either activated charcoal or amberlite resin.^{62,95} However, camphor has a very large volume of distribution (2–4 L/kg), and these cases documented only a small percentage of

body load effectively being removed, thus limiting its utility.

- **Clove oil:** In patients who exhibit signs of hepatotoxicity, NAC should be administered. Although no definitive studies on NAC use in this patient population are available, the suggestion that NAC is protective in the rat model, combined with the safety profile of NAC, warrant its use in the setting of eugenol-induced hepatotoxicity.⁸⁰
- **Pennyroyal:** One case of ingestion of a potentially fatal amount of pennyroyal was successfully treated with lavage, activated charcoal, and NAC.⁵ Given in vitro studies showing glutathione depletion, it would be reasonable to administer NAC in cases of pennyroyal-induced hepatotoxicity. Because there is no established dosing regimen, using the same regimen used for APAP toxicity would be reasonable.¹⁴⁸
- **Oil of wintergreen:** Alkalization with sodium bicarbonate and hemodialysis may be indicated in cases of severe toxicity. Exchange transfusion has been used successfully in children with life-threatening toxicity following methyl salicylate overdose ([Chap. 39](#)).⁴⁷

SUMMARY

- Essential oils are increasingly used as an alternative form of medical therapy.
- These oils contain mixtures of complex hydrocarbons that have the potential to be toxic.
- Cutaneous use of these products in moderation is associated with minimal toxicity. However, ingestion, prolonged inhalation, or excessive topical use may cause significant morbidity and mortality.
- Patients and health care providers should have open dialogues about the therapeutic use of these products and any concerning exposures should be referred to the regional poison centers for guidance in management.

44 FOOD POISONING

Michael G. Tunik

Each year in the United States there are approximately 9.4 million illnesses, 55,961 hospitalizations, and 1351 deaths from known foodborne agents, and 38.4 million gastroenteritis illnesses, 71,878 hospitalizations, and 1686 deaths from unspecified agents.³⁹ Worldwide food distribution, large-scale national food preparation and distribution networks, limited food regulatory practices, and corporate greed place everyone at risk. Food poisoning causes morbidity and mortality by one or more of the following mechanisms: Infectious agents (bacteria, viruses, parasites) can be transmitted in food; toxins, produced by organisms, can be consumed in food; toxins or chemicals can be inadvertently or purposefully used to contaminate food and be ingested.

This chapter is organized into four major types of food poisoning: foodborne poisoning with neurologic effects, food poisoning with gastrointestinal symptoms, foodborne poisoning with anaphylaxislike effects, and food poisoning used for bioterrorism.

HISTORY AND EPIDEMIOLOGY

In recent years in the United States, *Salmonella* spp and *Escherichia coli* have become the major causes of food poisoning responsible for epidemics that afflict millions, hospitalize hundreds, and kill many unsuspecting people.

The most common causes of foodborne disease include bacteria—*Salmonella* spp, *Campylobacter* spp, *Shigella* spp, and *E. coli*⁶⁶ (Table 44–1). In the last decade, large numbers of people have also suffered from food poisoning due to purposeful placement of chemicals in food,⁴¹ and staphylococcal toxin.¹⁵⁴

TABLE 44–1. Epidemiology of Food Poisoning Reported to the US Centers for Disease Control and Prevention (2009–2010)⁶⁶

<i>Etiology</i>	<i>Cases</i>	<i>Hospitalizations</i>
<i>Bacillus cereus</i>	427	3
<i>Campylobacter</i> spp	600	22
Ciguatoxin	61	6
<i>Clostridium perfringens</i>	3225	9
Hepatitis A virus	47	19
Mushroom poisoning	8	0
Norwalk virus	9737	109
Pesticides	42	2
<i>Salmonella</i> spp	7089	583
Scombrototoxin	76	0
<i>Shigella</i> spp	508	19
<i>Staphylococcus aureus</i>	252	0
<i>Vibrio</i> spp	82	43

FOODBORNE POISONING WITH NEUROLOGIC SYMPTOMS

The differential diagnosis of patients with foodborne poisoning presenting with neurologic symptoms is vast (Tables 44–2 and 44–3). The sources of many of these cases are ichthyosarcotoxic, involving toxins from the muscles, viscera, skin, gonads, and mucous surfaces of the fish; rarely, toxicity follows consumption of the fish blood or skeleton. Shellfish poisoning also must be considered. Most episodes of poisoning are not species specific, although particular forms of toxicity from Tetraodontiformes (puffer fish), Gymnothoraces (moray eel), and newts (*Taricha* and other species) are recognized.

TABLE 44–2. Differential Diagnosis of Possible Foodborne Poisoning Presenting with Neurologic Findings^a

Anticholinergic poisoning

Bacterial food poisoning

Botulism

Eaton-Lambert syndrome

Marine food poisoning (ciguatera, scombroid, tetrodotoxin)

Metals (arsenic, lead, mercury)

Monosodium glutamate

Organic phosphorous compounds

Plant xenobiotics (poison hemlock, buckthorn)

Tick paralysis

^aAltered mental status, motor weakness, sensory changes.

TABLE 44–3. Common Toxicologic Foodborne Neurologic Diseases (Primary Presenting Symptoms)

	<i>Onset/Duration*</i>	<i>Findings</i>	<i>Toxin Source/Toxin*/Mechanism**</i>	<i>Diagnosis**/Therapy*</i>
Ciguatera	2–24 hours *Months to years	t, p, n, v, d	Large reef fish: amber jack, barracuda, snapper, parrot, sea bass, moray (dinoflagellate, source) *Ciguatera toxin **Increased sodium channel permeability	**Clinical, mouse bioassay, immunoassay *Supportive, mannitol, isotonic saline Amitriptyline
Tetrodotoxin	Minutes to hours *Days	p, r, ↓bp	Puffer fish, flugu, blue-ringed octopus, newts, horseshoe crab *Tetrodotoxin **Blocks sodium channel	**Clinical *Respiratory support
Neurotoxic shellfish poisoning	15 min to 18 hours *Days	b, t, n, v, d, p	Mussels, clams, scallops, oysters, <i>P. brevis</i> : “red tide” *Brevetoxin **Increased sodium channel permeability	**Clinical, mouse bioassay of food, HPLC *Supportive
Paralytic shellfish poisoning	30 min *Days	t, p, n, v, d	Mussels, clams, scallops, oysters, <i>P. catenella</i> , <i>P. tamarensis</i> *Saxitoxin **Decreases sodium channel permeability	**Clinical, mouse bioassay of food, HPLC *Respiratory support
Amnesic shellfish poisoning	15 min to 38 hours *Years	a, n, v, d, p, r	Mussels, possibly other shellfish; <i>N. pungens</i> *Domoic acid **Glutamate analog	**Clinical, mouse bioassay of food, HPLC *Respiratory support
Botulism	12–73 hours *Years	v, d, t, w	Home-canned foods, honey, corn syrups, <i>C. botulinum</i> *Botulinum toxin **Binds presynaptically, blocks acetylcholine release	**Clinical immunoassay *Antitoxin, respiratory support

↓bp = hypotension; a = amnesia; b = bronchospasm; d = diarrhea; HPLC = high-pressure liquid chromatography; n = nausea; p = paresthesia; r = respiratory depression; t = temperature reversal sensation; v = vomiting; w = weakness.

In cases of ciguatera poisoning, the major symptoms usually are neurotoxic, and the gastrointestinal (GI) symptoms are minor. Scombroid poisoning, which is exceptionally common, is not associated with focal neurologic manifestations, but facial flushing, headache, and dysphagia are its major signs and symptoms.

Knowing where the fish was caught often helps establish a diagnosis, but refrigerated transport of foods and rapid worldwide travel can complicate that assessment. Travelers to Caribbean and Pacific islands, as well as those traveling

within the United States, have experienced ciguatera poisoning.⁹⁶ In geographically disparate regions of Canada,¹³⁰ individuals have experienced domoic acid poisoning due to ingestion of cultivated mussels from Prince Edward Island.

In the differential diagnosis of foodborne poisons presenting with neurologic findings, activities other than eating must always be considered. In particular, sport divers often perform their activities in high-risk areas such as Florida, California, and Hawaii, and often during the high-risk periods from May through August. In the process, they may sustain a sting from a stingray tail, or laceration (from a deltoid or pectoral fin spine of a lionfish or stonefish) that can cause consequential marine toxicity (Chap. 119).

Ciguatera Poisoning

Ciguatera poisoning is one of the most commonly reported forms of vertebrate fishborne poisonings in the United States accounting for almost one-half of the reported cases.⁶⁶ Ciguatera poisoning is endemic to warm water, bottom dwelling reef fish living around the globe between 35° north and 35° south latitude, which includes tropical areas such as the Indian Ocean, the South Pacific, and the Caribbean. Hawaii and Florida report 90% of all cases occurring in the United States, most commonly from May through August.⁹⁸

More than 500 fish species have caused human cases of ciguatera poisoning, with the barracuda, sea bass, parrot fish, red snapper, grouper, amber jack, kingfish, and sturgeon the most common sources. The common factor is the comparably large size of the fish involved.

Large fish (4–6 lb or more) become vectors of ciguatera poisoning in accordance with complex feeding patterns inherent in aquatic life. Ciguatoxin can be found in blue-green algae, protozoa, and the free algae dinoflagellates. These plankton members of the phylum Protozoa are single-celled, motile, flagellated, pigmented organisms thriving through photosynthesis. Photosynthetic dinoflagellates such as *Gambierdiscus toxicus* and bacteria within the dinoflagellates are the origins of ciguatoxin.^{51,77,104} Dinoflagellates are the main nutritional source for small herbivorous fish, which, in turn, are the major food source for larger carnivorous fish, thereby increasing the ciguatoxin concentrations in the flesh, adipose tissue, and viscera of larger and larger fish.¹¹

Ciguatoxin is heat stable, lipid soluble, acid stable, odorless, and tasteless. When purified, the toxin is a large (molecular weight: 1100 Da) complex ester that does not harm the fish but is stored in its tissues.^{100,105} The molecule binds to voltage-sensitive sodium channels in diverse tissues and increases the sodium permeability of the channel.^{10,159} The ciguatoxins cause hyperpolarization and a shift in the voltage dependence of channel activation, which opens the sodium channels. Ciguatoxins bind selectively to a particular binding site on the neuron's voltage-sensitive sodium channel protein.¹⁰³

Multiple ciguatoxins are identified in the same fish, perhaps explaining the variability of symptoms and differing severity.¹⁰⁴ People can be afflicted after eating fresh or frozen fish that was prepared by all common methods: boiling, baking, frying, stewing, or broiling. The appearance, taste, and smell of the ciguatoxic fish are usually unremarkable. The majority of symptomatic episodes begin 2 to 6 hours after ingestion, 75% within 12 hours, and 96% within 24 hours.¹¹ Symptoms include acute onset of diaphoresis; headaches, abdominal pain with cramps, nausea, vomiting; profuse watery diarrhea; and a constellation of dramatic neurologic symptoms.¹⁷⁵ A sensation of loose or painful teeth may occur. Typically, peripheral dysesthesias and paresthesias predominate. Watery eyes, tingling, and numbness of the tongue, lips, throat, and perioral area occur. A strange metallic taste is frequently reported as is a reversal of temperature discrimination, the pathophysiology of which remains to be elucidated.²⁸ Myalgias, most often in the lower extremities, arthralgias, ataxia, and weakness are commonly experienced.¹¹

Dysuria⁶⁴ and symptoms of dyspareunia and vaginal and pelvic discomfort may occur in women after sexual intercourse with men who are ciguatoxic and whose semen contains the toxin.⁹⁵ Vertigo, seizures, and visual disturbances such as blurred vision, scotomata, and transient blindness) are reported.

Bradycardia and orthostatic hypotension are described.⁶⁰ The GI symptoms usually subside within 24 to 48 hours; however, cardiovascular and neurologic symptoms may persist for several days to weeks, depending on the amount of toxin ingested. Delayed effects may include protracted itching and hiccoughs. Although deaths are reported, internationally none have been documented in the United States.⁶⁶ When it occurs, mortality is a result of respiratory paralysis and seizures not managed with adequate life support. Ciguatoxin may be transmitted in breast milk²⁰ and can cross the placenta.¹²⁸

Laboratory analysis using an enzyme-linked immunosorbent assay (ELISA) test for ciguatera toxin can be performed; alternatively, high-pressure liquid chromatography (HPLC) is accurate. A dipstick immunobead assay test being developed for field use will allow testing of fish without laboratory processing of the toxin-containing tissues.^{10,75,127} A useful approach to diagnosis and management includes laboratory testing to exclude other diagnostic possibilities and determine the need for, or extent of, specific therapeutic interventions.

Initial treatment for victims of ciguatoxin poisoning includes standard supportive care for a toxic ingestion.¹⁷⁵ In most patients, elimination of the toxin is accelerated if vomiting (40%) and diarrhea (70%) have occurred. Administration of

activated charcoal may be of some benefit. In patients with significant GI fluid loss through vomiting, diarrhea, or both, intravenous fluid and electrolyte repletion are essential. The orthostatic hypotension may respond to intravenous fluids and α -adrenergic agonists. Bradycardia may be treated with atropine.⁵⁷

Intravenous mannitol may alleviate neurologic and muscular dysfunctional symptoms associated with ciguatera; however, GI symptoms are not ameliorated.^{126,129} In one randomized controlled trial, mannitol failed to produce any greater improvement in symptoms than did intravenous 0.9% sodium chloride solution.¹⁴⁷ Mannitol should be used with caution because it may cause hypotension. Vascular reexpansion and cardiovascular stability should be initial treatment priorities. Mannitol may work by inhibiting the ciguatoxin-induced opening of sodium channels on the neuron membranes or reducing the neural edema via an osmotic gradient.

Admission to the hospital for cautious supportive care is essential when the diagnosis is uncertain or when volume depletion or any consequential manifestations are present (Tables 44–2 and 44–3). The etiology of the symptoms must be rapidly identified to provide specific therapy, if available. Diaphoresis is a common clinical finding and an important factor in the differential diagnosis. Late in the course of ciguatera poisoning, amitriptyline 25 mg orally twice daily may alleviate symptoms,²³ which may persist up to 1 year. Victims recovering from ciguatera should avoid alcohol and nuts for 3 to 6 months if exposure exacerbates symptoms.

Ciguateralike Poisoning

Moray, conger, and anguillid eels carry a ciguatoxinlike neurotoxin in their viscera, muscles, and gonads that does not affect the eel itself. The toxin is a complex ester that may be structurally very similar to ciguatoxin and is heat stable.¹²³ Individuals who eat these eels may manifest neurotoxic symptoms similar to ciguatoxin or may show signs of cholinergic toxicity, such as hypersalivation, nausea, vomiting, and diarrhea. Shortness of breath, mucosal erythema, and cutaneous eruptions may also occur. These findings may be present in addition to the neurotoxic symptoms.⁷¹ Management is supportive. Mortality is related to the complications of neurotoxicity, such as seizures and respiratory paralysis.

Shellfish Poisoning

Healthy mollusks living between 30° North and 30° South latitude ingest and filter large quantities of dinoflagellates. These dinoflagellates are the major source of available ocean food during the “non-R” months (May through August) in the northern hemisphere. During this time, these dinoflagellates are responsible for the “red tides” that may be seen from California to Alaska, from New England to the St. Lawrence, and across the west coast of Europe.¹¹⁰ The number of toxic dinoflagellates may be so overwhelming that birds and fish die, and humans who walk along the beach may experience respiratory symptoms caused by aerosolized toxin.¹¹²

Ingestion of shellfish, including oysters, clams, mussels, and scallops, contaminated by dinoflagellates or algae may cause neurotoxic, paralytic, and amnesic syndromes. The dinoflagellates most frequently implicated are *Karenia brevis* (originally named *Gymnodinium breve* in 1948, renamed *Ptychodiscus brevis* in 1979, and reclassified again to the current nomenclature in 2000). The diatoms causing neurotoxic shellfish poisoning include *Protogonyaulax catenella* and *Protogonyaulax tamarensis*, which cause paralytic shellfish poisoning; and *Nitzschia pungens*, the diatom implicated in amnesic shellfish poisoning. Proliferation of these diatoms may cause a red tide, but shellfish poisoning may occur even in the absence of this extreme proliferation.

Paralytic shellfish poisoning is caused by saxitoxin. Saxitoxin blocks the voltage-sensitive sodium channel in a manner identical to tetrodotoxin (TTX; see later). The shellfish implicated usually are clams, oysters, mussels, and scallops, but poisoning has occurred through consumption of crustaceans, gastropods, and fish.

The higher the number of shellfish consumed, the more severe the symptoms. Symptoms usually occur within 30 minutes of ingestion. Neurologic effects predominate and include paresthesias and numbness of the mouth and extremities, a sensation of floating, headache, ataxia, vertigo, muscle weakness, paralysis, and cranial nerve dysfunction manifested by dysphagia, dysarthria, dysphonia, and transient blindness. GI symptoms are less common and include nausea, vomiting, abdominal pain, and diarrhea. Fatalities may occur as a result of respiratory failure, usually within the first 12 hours after symptom onset. Muscle weakness may persist for weeks.

Treatment is supportive. Early intervention for respiratory failure is indicated. Orogastric lavage and cathartics were used to remove unabsorbed toxin from the GI tract but probably are not necessary or efficacious.^{26,101,116,152} Activated charcoal may be given. Antibodies against saxitoxin have reversed cardiorespiratory failure in animals,¹⁴ but this therapy is not yet available for humans. Assays for saxitoxin include a mouse bioassay, ELISA, and HPLC. High-pressure liquid chromatography has good interlaboratory accuracy,¹⁷⁰ but the differences in saxitoxin derivatives make standardization of an analytic test difficult.^{9,97}

Neurotoxic shellfish poisoning (NSP) is caused by brevetoxin. Brevetoxin, which is produced by *Karenia brevis* (previously *Gymnodinium brevis*, and subsequently *Ptychodiscus brevis*), is a lipid-soluble, heat-stable polyether toxin similar to ciguatoxin. It acts by stimulating sodium flux through the sodium channels of both nerve and muscle.^{6,29} NSP is

characterized by gastroenteritis with associated neurologic symptoms. GI symptoms include abdominal pain, nausea, vomiting, diarrhea, and rectal burning. Neurologic features include paresthesias, reversal of hot and cold temperature sensation, myalgias, vertigo, and ataxia. Other effects may include headache, malaise, tremor, dysphagia, bradycardia, decreased reflexes, and dilated pupils. Paralysis does not occur. The combination of bradycardia and mydriasis is unusual. The incubation period is 3 hours (range 15 minutes to 18 hours). GI and neurologic symptoms appear simultaneously. Other manifestations of brevetoxin poisoning include mucosal irritation, cough, and bronchospasm, which occur when *P. brevis* is aerosolized by wave action during red tides. The duration of effects averages 17 hours (range 1–72 hours).¹¹⁶

Brevetoxins can be assayed using mouse bioassay, ELISA, and, more recently, antibody radioimmunoassay and reconstituted sodium channels.^{132,167} Treatment is supportive, and severe respiratory depression is very uncommon. Therapy includes removal of the patient from the environment and the administration of bronchodilators. Neurotoxic shellfish poisoning is not fatal.

Amnesic shellfish poisoning is caused by domoic acid, a structural analogue of glutamic and kainic acids produced by the diatom *N. pungens*. The most extensively documented human outbreak occurred in Canada in 1987, when 107 individuals who had consumed mussels harvested from cultivated river estuaries on Prince Edward Island were affected.¹³⁰ Other human outbreaks may have occurred due to a similar diatom—*Pseudonitzschia australis*—which has been isolated in shellfish from other areas.⁵⁸ Pelican deaths caused by domoic acid-laden anchovies were reported in 1991 and Canada instituted monitoring for domoic acid after this outbreak.¹⁶⁴ The death of 400 sea lions in California in 1998 was linked to domoic acid from the same diatom.¹⁴⁸

Amnesic shellfish poisoning is characterized by GI symptoms of nausea, vomiting, abdominal cramps, diarrhea, and by neurologic symptoms of memory loss and, less frequently, coma, seizures, hemiparesis, ophthalmoplegia, purposeless chewing, and grimacing. Other signs and symptoms include hemodynamic instability and cardiac dysrhythmias. Symptoms typically begin 5 hours (range 15 minutes to 38 hours) after ingestion of mussels. The mortality rate is 2%, with death most frequently occurring in older patients, who experience more severe neurologic symptoms. Ten percent of victims may have long-term antegrade memory deficits, as well as motor and sensory neuropathy. Postmortem examinations have revealed neuronal damage in the hippocampus and amygdala.¹⁶³

Tetrodotoxin Poisoning

This type of fish poisoning involves only the order Tetraodontiformes. Although this order of fish is not restricted geographically, it is eaten most frequently in Japan, California, Africa, South America, and Australia.⁷¹ Cases have also occurred in Florida and New Jersey, as well as Europe, the Mediterranean, and Bangladesh. Approximately 100 freshwater and saltwater species exist in this order, including a number of pufferlike fish such as the globe fish, balloon fish, blowfish, and toad fish.¹¹⁸ TTX found in these fish is also isolated from the blue-ringed octopus⁵⁵ and the gastropod mollusk,¹⁷⁷ and has also been responsible for fatalities from ingestion of horseshoe crab eggs.⁸¹ Certain TTX containing newts (*Taricha*, *notophthalmus*, *triturus*, and *cynops*), particularly *Taricha granulosa*, found in Oregon, California, and southern Alaska, can be fatal when ingested. Most newts and salamanders with bright colors and rough skins contain toxins.²⁴ In Japan, fugu (a local variety of puffer fish) is considered a delicacy, but special licensing is required to prepare this exceedingly toxic fish. In 1989, the US Food and Drug Administration (FDA) legalized the importation of puffer fish. However, prior to exportation from Japan, the fish must be laboratory tested and certified by two Japanese organizations to be free of TTX.

TTX is a heat-stable (except in alkaline milieu), water-soluble nonprotein, found mainly in the fish skin, liver, ovary, intestine, and possibly muscle.^{71,143} The ovary has a high concentration of the toxin and is most poisonous if eaten during the spawning season. TTX is detected by mouse bioassay. It is unstable when heated to 212°F (100°C) in acid, distinguishing it from saxitoxin. TTX from fish can be detected using fluorescent spectrometry⁹ or from the urine of poisoned patients using a combination of immunoaffinity chromatography and fluorometric HPLC.⁸²

TTX and saxitoxin are produced by marine bacteria and likely accumulate in animals higher on the food chain that consume these bacteria.¹²² Accumulation of toxins, primarily in the skin, of two species of Asian puffer fish has been documented. Whether this accumulation of toxin is simply an evolutionary adaptation, to remove a toxic substance, or one that has evolutionary advantages of protection is unclear.¹²¹

Neurotoxicity is produced by inhibition of sodium channels and blockade of neuromuscular transmission.^{119,120} The sodium channel is blocked from the external surface of the neuron by the TTX molecule, which contains a guanidinium group that fits into the external orifice of sodium channel. This causes external “plugging” of the sodium channel, although the gating mechanism is functional.^{119,120}

Effects of tetrodotoxin poisoning typically occur within minutes of ingestion. Headache, diaphoresis, dysesthesias, and paresthesias of the lips, tongue, mouth, face, fingers, and toes evolve rapidly. Buccal bullae and salivation may develop. Dysphagia, dysarthria, nausea, vomiting, and abdominal pain may ensue. Generalized malaise, loss of coordination, weakness, fasciculations, and an ascending paralysis (with risk of respiratory paralysis) occur in 4 to 24 hours. Other

cranial nerves may be involved. In more severe toxicity, hypotension is present. In some studies, mortality has approached 50%.¹⁵⁵

Therapy is supportive. Removal of the toxin and prevention of absorption are the essential measures. Supportive respiratory care emphasizing airway protection, including intubation, if necessary, is extremely important.

Less Common Poisonings: Echinoderms

The sea urchin usually causes toxicity by contact with its spinous processes, but this Caribbean delicacy also is toxic upon ingestion. When the sea urchin is prepared as food, the venom containing gonads should be removed because they contain an acetylcholinelike substance that causes the cholinergic syndrome of profuse salivation, abdominal pain, nausea, vomiting, and diarrhea. The sea star is considered edible by some individuals, although an asteriotoxin with saponinlike activity that produces nausea and vomiting is reported.

PREVENTION OF MARINE FOODBORNE DISEASE

Careful evaluation of the symptoms and meticulous reporting to local and state health departments, as well as to the US Centers for Disease Control and Prevention (CDC), will allow for more precise analysis of epidemics of poisoning from contaminated or poisonous food or fish. Many states and countries have developed rigorous health codes with regard to harvesting certain species of fish in certain areas at certain times.

Some examples of actions taken by state and foreign health agencies in controlling epidemics of seafood-borne food poisoning are the following: A 3230-km stretch of Massachusetts coastline was noted to be unsafe for shellfish harvesting due to a red tide bloom. The state declared a health emergency and confiscated shellfish harvested in this area, and prohibited the marketing, export, and serving of shellfish.¹⁰⁹ The health code of Miami, Florida, prohibits the sale of barracuda and warns against eating fillets from large and potentially toxic fish containing ciguatoxin. The Japanese closely regulate preparation and selling of the puffer fish (fugu), requiring that preparers receive special training and licensing. The sale of fugu is now also permitted under strict control in the United States as well. The Canadian government marks the location and time of harvesting of mussels, and mussels are tested for the presence of domoic acid.^{58,130}

FOOD POISONING ASSOCIATED WITH DIARRHEA

The initial differential diagnosis for acute diarrhea involves several etiologies: infectious (bacterial, viral, parasitic, and fungal), structural (including surgical), metabolic, functional, inflammatory, toxin induced, and food induced. The differential diagnosis is described in greater detail in [Chap. 20](#).

An elevated temperature may be caused by invasive organisms, including *Salmonella* spp, *Shigella* spp, *Campylobacter* spp, invasive *E. coli*, *Vibrio parahaemolyticus*, and *Yersinia* spp, as well as some viruses. Episodes of acute gastroenteritis not associated with fever can be caused by organisms producing toxins, including *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, enterotoxigenic *E. coli*, and viruses.³

Fecal leukocytes typically are found in patients with invasive shigellosis, salmonellosis, *Campylobacter* enteritis, typhoid fever, invasive *E. coli* colitis, *V. parahaemolyticus*, *Yersinia enterocolitica*, and inflammatory bowel disease. In all of these conditions, except typhoid fever, the leukocytes are primarily polymorphonuclear; in typhoid fever, they are mononuclear. No stool leukocytes are noted in cholera, viral diarrhea, noninvasive *E. coli* diarrhea, or nonspecific diarrhea.⁷⁴

The timing of diarrhea onset after exposure or the incubation period can be useful in differentiating the cause. Extremely short incubation periods of less than 6 hours are typical for *Staphylococcus*, *B. cereus* (type I), enterotoxigenic *E. coli*,^{3,107,162} and preformed enterotoxins, as well as roundworm larvae ingestions. Intermediate incubation periods of 8 to 24 hours are found with *C. perfringens*, *B. cereus* (type II enterotoxin), enteroinvasive *E. coli*,^{49,114} and salmonella. Longer incubation periods occur in other bacterial causes of acute gastroenteritis ([Table 44–4](#)).

TABLE 44–4. Common Foodborne Infections: Gastrointestinal (Time of Onset and Primary Presenting Symptom)

Etiology	Onset	Symptoms					Source	Pathogenesis	Therapy
		A	V	Di	Dy	F			
<i>Staphylococcus</i> spp	2–6 hours	+	+	+	–	–	Prepared foods: meats, pastries, salads	Heat stable enterotoxin	Supportive, volume expansion
<i>Bacillus cereus</i>									
Type I	1–6 hours	+	+	+	–	–	Fried rice	Heat labile toxins	Supportive, volume expansion
Type II	12 hours	+	–	+	–	–	Meats, vegetables	Heat labile toxins	
Anisakiasis	1–12 hours	+	+	–	–	–	Raw fish, sushi, (Eustrongyloides), minnows, salmon, cod, herring, squid, tuna	Intestinal larvae	Endoscopy, laparotomy removal
<i>Clostridium perfringens</i>	8–24 hours	+	±	+	±	–	Poultry, heat-processed meats	Heat labile enterotoxin	Volume expansion
<i>Salmonella</i> spp	8–24 hours	±	±	+	±	+	Poultry, egg, pets (turtles, lizards, chicks)	Bacteria, endotoxin (bacteremia)	Antibiotics
<i>E. coli</i>	24–72 hours						Water, food	Enterotoxin, heat stable	Volume expansion
Enterotoxigenic	<6 hours	+	±	+	–	+	Enteric contact		Electrolytes
Invasive	24–72 hours	+	–	+	+	+	Raw produce	Bacteria (invasive)	Antibiotics
Hemorrhagic	24–72 hours	+	+	+	+	±	Under cooked beef, unpasteurized milk	Shiga-like toxin	Renal, hematologic support
<i>Vibrio cholera</i>	24–72 hours	±	±	+	–	±	Water, food enteric contact	Heat labile Enterotoxin	Electrolyte replacement, antibiotics
<i>Shigella</i> spp	24–72 hours	+	±	+	+	±	Institutional food handlers, household, preschool, enteric contact	Bacteria-Endotoxin	Antibiotics
<i>Campylobacter jejuni</i>	1–7 days	+	+	+	±	+	Milk, poultry, unchlorinated water	Bacteria, heat labile enterotoxin	Antibiotics
<i>Yersinia</i> spp	1–7 days	+	+	+	±	+	Pork, milk, pets	Bacteria, enterotoxin	Antibiotics

A = abdominal pain; Di = diarrhea; Dy = dysentery; F = fever; V = vomiting.

The three most likely etiologies of diarrhea are infectious, xenobiotics (chemicals found in an organism, not normally present, frequently a pollutant or contaminant), and foodborne. These three etiologies are not mutually exclusive. The differential diagnosis must be made among these groups. When the time from exposure to onset of symptoms is brief, all of the nonbacterial infectious etiologies (viral, parasitic, fungal, and algal) except for upper GI invasion by roundworm larvae can be eliminated. The possibility of a bacterial etiology with enterotoxin production should be considered (Table 44–4).^{3,21}

EPIDEMIOLOGY

Epidemiologic analysis is of immediate importance, particularly when GI diseases strike more than one person in a group. The questions raised in Table 44–5 must be answered.¹⁴² If available, an infectious disease consultant or infection control officer should be called for assistance. Alternatively, assistance from state and local health departments should be sought. Often, only the CDC or state health department has the resources to investigate and confirm a presumptive diagnosis in an outbreak. Sophisticated techniques such as toxin detection, matching the organism in the food by phage type with a food handler, matching an organism by phage type with other persons, isolating 10 or more organisms per gram of implicated food,^{49,52} or polymerase chain reaction (PCR) identification of bacterial or plasmid DNA are potentially useful, although generally not possible using the laboratory and personnel available in most hospitals.^{27,32,65} Structural, metabolic, and functional causes often can be eliminated. As in these diseases, neither a significant grouping of cases nor a limited clinical history is characteristic. Foodborne parasites such as *Trichinella spiralis* (trichinosis), *Toxoplasma gondii* (toxoplasmosis), and *G. lamblia* (giardiasis) must be considered, although acute GI symptoms are not usually prominent.

TABLE 44–5. Epidemiologic Analysis of Gastrointestinal Disease

1. Is the occurrence of the disease in a large group significant enough to be consistent with foodborne disease (two or more cases)?
2. Is the symptomatology in affected individuals well defined and similar?
3. Is the onset, time, and duration of illness similar among affected group members (incubation)?
4. What are the possible modes of transmission (ie, contact, food, water)?
5. Is there a relationship between the time of exposure of the group and the mode of transmission?
6. Do attack rates differ for age, gender, or occupation?
7. Can it be determined which foods were served and to whom? Can the items that were not eaten by those who did not become ill be identified?
8. What is the food-specific attack rate?
9. How was the food procured? How was it stored?
10. Was cooking technique adequate?
11. Was personal hygiene acceptable?
12. Was there animal contamination?

Salmonella Species

Salmonella enteritidis infections are of great concern in the United States. Two particular outbreaks define very special problems. In the 1980s, recurrent outbreaks associated with grade A eggs or food containing such eggs occurred. In the past, such outbreaks of salmonella enteritis were attributed to infection of the egg with salmonella (from the chicken's GI tract) through cracks in the shell. More recently, outbreaks have involved noncracked, nonsoiled eggs.¹¹⁵ In these cases, presumably the salmonella has infected the eggs before the shell was formed. In either case, people who consume raw or undercooked eggs are at most risk for salmonella enteritis. Raw eggs can be found as ingredients of chocolate mousse, hollandaise sauce, eggnog, Caesar salads, and homemade ice cream. Whole, partially cooked eggs are problematic when eaten sunny side up or poached.³⁷ The second group of outbreaks was associated with raw milk,¹³³ which has become very popular in certain communities. Inadequate microwave cooking may cause small outbreaks.⁵³ These outbreaks are of great concern because they frequently involve multiple drug resistant salmonella infections.⁴⁵ Drinking pasteurized milk may not be protective. An outbreak of salmonellosis resulting in more than 16,000 culture-proven cases was traced to one Illinois dairy. The probable cause of the outbreak was a transfer line connecting raw and pasteurized milk containment tanks.¹³⁹

The contamination of food that is widely distributed places thousands at risk. An outbreak of salmonella food poisoning from peanut butter caused 529 confirmed illnesses in 48 states and Canada, 116 hospitalizations, and possibly eight deaths.⁴⁰ The CDC estimates that the proportion of salmonella infections that are confirmed by laboratory testing is 3% of the total, so the estimated number of infected people affected by this contamination incident may be more than 15,000. News reports state that the peanut butter contamination with salmonella was known, and that the peanut butter was retested for contamination, until no salmonella was reported. The peanut butter was then nationally distributed.⁷³

Additional concern has developed over the widespread use of anti-biotics in animal feed, responsible for meats, poultry, and manure-fertilized vegetables now frequently containing resistant bacterial strains to which virtually the entire population may be exposed.^{45,139} "Household" pets such as chicks, turtles, and iguanas host salmonella and frequently transmit the organism to household contacts, including infants, who are at particular risk for invasive diseases, as well as other family members.¹

FOODBORNE POISONING ASSOCIATED WITH MULTIORGAN SYSTEM DYSFUNCTION

The hemolytic uremic syndrome (HUS) is frequently caused by a bacterial gastroenteritis. The most commonly responsible organism is *E. coli* O157:H7.⁶⁸ Other bacteria and xenobiotics cause the same findings. Typical laboratory findings in HUS include microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney injury.

HUS begins with a prodrome of diarrhea 90% of the time. The diarrhea lasts for 3 to 4 days and frequently becomes bloody. Abdominal pain due to colitis is common, and vomiting, altered mental status (irritability or lethargy), pallor, and low-grade fever frequently occur. At presentation, many have oliguria or anuria, and 10% of children have a generalized seizure at HUS onset.¹⁵¹

HUS is frequently associated with enterohemorrhagic *E. coli* (EHEC) or *E. coli* O157:H7 with postdiarrheal HUS.^{25,109,124,125,137,172} Food products from cattle (ground beef, milk, yogurt, cheese) and water contaminated with fecal

material are EHEC sources.^{48,111} Contaminated water used in gardens and unpasteurized apple cider have caused bloody diarrhea and HUS as a result of EHEC.^{16,44}

EHEC, including *E. coli* O157:H7, produces a toxin similar to the toxin produced by *Shigella dysenteriae* type I, referred to as Shiga-like toxin (SLT) or verotoxin.²¹ The proposed mechanism for SLT damage is intestinal absorption, bloodstream access to renal glomerular endothelium, intracellular adsorption via glycolipid receptors, ribosomal inactivation, and cell death.¹⁶¹ In animal models, organ damage is more severe if endothelial cells have high concentrations of globotriaosylceramide receptors, which have a high binding affinity for Shiga toxin. Other organs with these receptors include the kidney, GI, and central nervous systems, which may explain the pattern of organ damage in children with HUS. Endothelial cell damage and other pathologic processes, including platelet and leukocyte activation, triggering of the coagulation cascade, and the production of cytokines, occur.^{83,169} More than one type of SLT exists; SLT-1, SLT-2, and variants of SLT-2 structure are identified.¹⁷

Detection of *E. coli* O157:H7 through stool culture early in the course of disease is useful. The recovery decreases after the first week of illness.¹⁶¹ *E. coli* O157:H7 almost always produces SLT; therefore, if stool cultures are negative, enzyme immunoassay (EIA) and PCR tests can be used to detect SLT in the stool when *E. coli* can no longer be identified by culture.²⁷

Treatment of HUS should focus on meticulous supportive care, with fluid and electrolyte balance the priority. Dialysis should be instituted early for azotemia, hyperkalemia, acidosis, and fluid overload. Red blood cells and platelet transfusions may be required. Hypertension should be treated with short-acting calcium channel blockers (nifedipine 0.25–0.5 mg/kg/dose orally) and seizures with benzodiazepines. Plasmapheresis has been used in nondiarrheal HUS and in recurrent HUS after renal transplants. Anti-SLT-2 antibodies have protected mice from SLT-2 toxicity, but intravenous immunoglobulin with SLT-2 activity has not improved outcome in children with HUS. A double-blind, placebo-controlled study on the use of synthetic SLT receptors attached to an oral carrier found that mortality or serious morbidity of HUS syndrome did not change as a result.¹⁶⁶

The mortality from HUS with good supportive care is approximately 5%; another 5% of victims suffer end-stage kidney disease or cerebral ischemic events and chronic neurologic impairment. Prolonged anuria (>1 week), oliguria (>2 weeks), or severe extrarenal disease may serve as markers for higher mortality and morbidity.¹³¹

There is some evidence that early treatment with antibiotics increases the risk of development HUS in children with *E. coli* O157:H7 infections.¹⁵⁶ An earlier meta analysis and randomized trial did not find this association.^{134,140} Due to this concern, many experts recommend not treating patients with clinical or epidemiologic presentations consistent with *E. coli* O157:H7 infections (crampy abdominal pain, bloody diarrhea, regional outbreak) until a definitive pathogen can be identified.

Strategies to prevent the spread of *E. coli* O157:H7 and subsequent HUS include public education on the importance of thorough cooking of beef to a “well-done” temperature of 170°F (77°C), pasteurization of milk and apple cider, and thorough cleaning of vegetables. Public health measures include education of clinicians to consider *E. coli* O157:H7 in patients with bloody diarrhea and insuring the routine capability of microbiology laboratories to culture *E. coli* O157:H7 and provide for EIA or PCR determination of SLT. Public health departments should provide active surveillance systems to identify early outbreaks of *E. coli* O157:H7 infection.

Staphylococcus Species

In cases of suspected food poisoning with a short incubation period, the physician should first assess the risk for staphylococcal causes. The usual foods associated with staphylococcal toxin production include milk products and other proteinaceous foods, cream-filled baked goods, potato and chicken salads, sausages, ham, tongue, and gravy. Pie crust can act as an insulator, maintaining the temperature of the cream filling and occasionally permitting toxin production even during refrigeration.⁴ A routine assessment must be made for the presence of lesions on the hands or nose of any food handlers involved. Unfortunately, carriers of enterotoxigenic staphylococci are difficult to recognize because they usually lack lesions and appear healthy.⁷⁶ A fixed association between a particular food and an illness would be most helpful epidemiologically but rarely occurs clinically. Factors such as environment, host resistance, nature of the agent, and dose make the results surprisingly variable.

Although patients with staphylococcal food poisoning rarely have significant temperature elevations, 16% of 2992 documented cases in a published review had a subjective sense of fever.⁷⁶ Abdominal pain, nausea followed by vomiting, and diarrhea dominate the clinical findings. Diarrhea does not occur in the absence of nausea and vomiting. The mean incubation period is 4.4 hours with a mean duration of illness of 20 hours. Two staphylococcal enterotoxin food poisoning incidents involving large numbers of people have been reported. At a public event in Brazil in 1998, one-half of the 8000 people who attended had nausea, emesis, diarrhea, abdominal pain, and dizziness within hours of consuming food. Of the ill patients, 2000 overwhelmed the capacity of local emergency departments, 396 (20%) were admitted including 81 to intensive care units, and 16 young children and elderly participants died.¹⁵⁴ In another report, 328 individuals became ill

with symptoms of diarrhea, vomiting, dizziness, chills, and headache after eating cheese or milk.¹⁵³ In both reports, staphylococcus enterotoxin was found in the food consumed.

Most enterotoxins are produced by *S. aureus* coagulase-positive species. The enterotoxins initiate an inflammatory response in GI mucosal cells and lead to cell destruction. The enterotoxins also may exert a sudden explosive effect on the emesis center in the brain and diverse other organ systems. Discrimination of unique *S. aureus* isolates from those found in foodborne outbreaks can be made using restriction fragment length polymorphism analysis by pulsed-field gel electrophoresis and PCR techniques.¹⁷³

Bacillus cereus

Another foodborne toxin with GI symptoms is associated with eating reheated fried rice. *Bacillus cereus* type I is the causative organism, and bacterial overgrowth and toxin production causes consequential early onset nausea and vomiting.² Infrequently this toxin causes liver failure.¹⁰⁸ *Bacillus cereus* type II has a delayed onset of similar GI symptoms, including diarrhea.⁵⁹

Campylobacter jejuni

Campylobacter jejuni is a major cause of bacterial enteritis. The organism is most commonly isolated in children younger than 5 years and in adults 20 to 40 years of age. *Campylobacter* enteritis outbreaks are more common in the summer months in temperate climates. Although most cases of *Campylobacter* enteritis are sporadic, outbreaks are associated with contaminated food and water. The most frequent sources of *Campylobacter* in food are raw or undercooked poultry products⁵⁴ and unpasteurized milk.¹⁵⁷ Birds are a common reservoir, and small outbreaks are associated with contamination of milk by birds pecking on milk-container tops.¹⁵⁷ Contaminated water supplies are also frequent sources of *Campylobacter* enteritis involving large numbers of individuals.¹⁹ *C. jejuni* is heat labile; cooking of food, pasteurization of milk, and chlorination of water will prevent human transmission.

The incubation period for *Campylobacter* enteritis varies from 1 to 7 days (mean 3 days). Typical symptoms include diarrhea, abdominal cramps, and fever. Other symptoms may include headache, vomiting, excessive gas, and malaise. The diarrhea may contain gross blood, and leukocytes are frequently present on microscopic examination.⁷⁴ Illness usually lasts 5 to 6 days (range 1–8 days). Rarely, symptoms last for several weeks. Severely affected individuals present with lower GI hemorrhage, abdominal pain mimicking appendicitis, a typhoidlike syndrome, reactive polyarthritis (Reiter syndrome), or meningitis. The organism may be detected using PCR identification techniques.⁶² Treatment is supportive, and consists of volume resuscitation, and possibly antibiotics for the more severe cases.³

Group A Streptococcus

Bacterial infections not usually associated with food or food handling are nevertheless occasionally transmitted by food or food handling. Transmission of streptococcal pharyngitis in food prepared by an individual with streptococcal pharyngitis has been demonstrated.⁴⁶ A Swedish food handler caused 153 people to become ill with streptococcal pharyngitis when his infected finger wound contaminated a layer cake served at a birthday party.⁷

Clostridium botulinum

In the last 3 decades, a median of four cases of foodborne botulism, three cases of wound botulism, and 71 cases of infant botulism have been reported annually to the CDC.¹⁵⁰ Home-canned fruits and vegetables, as well as commercial fish products, are among the common foods causing botulism. The incubation period usually is 12 to 36 hours; typical symptoms include some initial GI symptoms, followed by malaise, fatigue, diplopia, dysphagia, and rapid development of small muscle incoordination.⁹⁸ In botulism, the toxin is irreversibly bound to the neuromuscular junction, where it impairs the presynaptic release of acetylcholine.⁹² A patient's survival depends on rapidly diagnosing botulism and immediate initiation of aggressive respiratory therapy. Establishing the diagnosis early may make it possible to treat the "sentinel" or index patient and also others who consumed the contaminated food with antitoxin prior to their developing signs and symptoms (Chap. 41 and Antidotes in Depth: A6). The differential diagnosis of botulism includes myasthenia gravis, atypical Guillain-Barré syndrome, tick-induced paralysis, and certain chemical ingestions (Tables 41–1 and 41–2).

Yersinia enterocolitica

Yersinia enterocolitica causes enteritis most frequently in children and young adults. Typical clinical features include fever, abdominal pain, and diarrhea, which usually contains mucus and blood.^{8,160,171} Other associated symptoms include nausea, vomiting, anorexia, and weight loss. The incubation period may be 1 to 7 days or more. Less common features include prolonged enteritis, reactive polyarthritis, pharyngeal and hepatic involvement, and rash. *Yersinia* is a common

pathogen in many animals, including dogs and pigs. Sources of human infection include milk products, raw pork products, infected household pets, and person-to-person transmission.^{22,70,99} The diagnosis may be based on cultures of food, stool, blood, and, less frequently, skin abscesses, pharyngeal cultures, or cultures from other organ tissues (mesenteric lymph nodes, liver). *Yersinia* may be identified by PCR.⁸⁴ Patients receiving the chelator deferoxamine (Antidotes in Depth: A7) may acquire *Yersinia* infections due to the patients' increased susceptibility. The deferoxamine-iron complex acts as a siderophore for organism growth. Therapy is usually supportive, but patients with invasive disease (eg, bacteremia, bacterial arthritis) should be treated with intravenous antibiotics. Fluoroquinolones and third-generation cephalosporins are highly bacteriocidal against *Yersinia* spp.

Listeria monocytogenes

Listeriosis transmitted by food usually occurs in pregnant women and their fetuses, the elderly, and immunocompromised individuals using corticosteroids or with malignancies, diabetes mellitus, kidney disease, or HIV infection.^{15,34,36,146} Typical food sources include unpasteurized milk, soft cheeses such as feta, and undercooked chicken. Individuals at risk should avoid the usual sources and should be evaluated for listeriosis if typical symptoms of fever, severe headache, muscle ache, and pharyngitis develop. Treatment with intravenous ampicillin and aminoglycoside, or trimethoprim/sulfamethoxazole is indicated for systemic *Listeria* infections.

Xenobiotic-Induced Diseases

In addition to the aforementioned saxitoxin TTX, domoic acid, and ciguatoxin, many other xenobiotics contaminate our food sources. Careful assessment for possible foodborne pesticide poisoning is essential. For example, aldicarb contamination has occurred in hydroponically grown vegetables and watermelons contaminated with pesticides.⁶⁷ Eating malathion-contaminated chapatti and wheat flour resulted in 60 poisonings including a death in one outbreak⁴² (Chap. 113). Insecticides, rodenticides, arsenic, lead, or fluoride preparations can be mistaken for a food ingredient. These poisonings usually have a rapid onset of signs and symptoms after exposure.

The possibility of unintentional acute metal salt ingestion must also be considered. This type of poisoning most typically occurs when very acidic fruit punch is served in metal-lined containers. Antimony, zinc, copper, tin, or cadmium in a container may be dissolved in an acidic food or juice medium.

Mushroom-Induced Disease

Some species produce major GI effects. *Amanita phalloides*, the most poisonous mushroom, usually causes GI symptoms as well as hepatotoxic effects with a delay to clinical manifestations. The rapid onset of symptoms suggests some of the gastroenterotoxic mushrooms (Chap. 120).

Intestinal Parasitic Infections

The popularity of eating raw fish, or sushi, has led to an increase in reported intestinal parasitic infections. Etiologic agents are roundworms (*Eustrongyloides anisakis*) and fish tapeworms (*Diphyllobothrium* spp). Symptoms of anisakiasis may be upper intestinal (occur 1–12 hours after eating) or lower intestinal (delayed for days or weeks). Typical symptoms include nausea, vomiting, and severe crampy abdominal pain; with intestinal perforation severe pain, rebound, and guarding occur. A dietary history of eating raw fish is needed to establish diagnosis and therapy. Visual inspection of the larvae (on endoscopy, laparotomy, or pathologic examination) is useful. Treatment of intestinal infection involves surgical or laparoscopic removal. *Anisakis simplex* and *Pseudoterranova decipiens* are Anisakidae that may be found in several types of consumed raw fish, including mackerel, cod, herring, rockfish, salmon, yellow fin tuna, and squid. Reliable methods of preventing ingestion of live anisakid larvae are freezing at –4°F (–20°C) for 60 hours or cooking at 140°F (60°C) for 5 minutes.^{31,89,106,138,144,176}

Diphyllobothriasis (fish tapeworm disease) is caused by eating uncooked fish that harbor the parasite, including herring, salmon, pike, and whitefish. The symptoms are less acute than with intestinal roundworm ingestions and usually begin 1–2 weeks after ingestion.³⁰ Signs and symptoms include nausea, vomiting, abdominal cramping, flatulence, abdominal distension, diarrhea, and megaloblastic anemia. The diagnosis is based on a history of ingesting raw fish and on identification of the tapeworm proglottids in stool. Treatment with niclosamide, praziquantel, or paromomycin usually is effective.³⁵

Monosodium Glutamate

This clinical presentation is misnamed “Chinese restaurant syndrome” since it results from the ingestion of monosodium glutamate (MSG), which has multicultural use in the preparation of many foods. Affected individuals present with a burning sensation of the upper torso, facial pressure, headache, flushing, chest pain, nausea and vomiting, and, infrequently, life-

threatening bronchospasm,³ and angioedema.¹⁵⁸ Intensity and duration of symptoms are generally dose related but with significant variation in individual responses to the amount ingested.^{145,178} MSG causes “shudder attacks” or a seizurelike syndrome in young children. Absorption is more rapid following fasting, and the typical burning symptoms rapidly spread over the back, neck, shoulders, abdomen, and occasionally the thighs. GI symptoms are rarely prominent and symptoms can usually be prevented by prior ingestion of food. When symptoms do occur, they tend to last approximately one hour. The syndrome is a reaction to MSG, which had been commonly used in Chinese and many other restaurants. MSG is also marketed as an effective flavor enhancer.¹³ Many sausages and canned soups contain large doses of MSG.

MSG (regarded as “safe” by the FDA) can cause other acute and bizarre neurologic symptoms. There is evidence that humans have a unique taste receptor for glutamate.⁹¹ This explains its ability to act as a flavor enhancer for foods. Glutamate is also an excitatory neurotransmitter that can stimulate central nervous system neurons through activation of glutamate receptors, and may be the explanation for some of the neurologic symptoms described with ingestion.¹⁷⁹

Anaphylaxis and Anaphylactoid Presentations

Some foods and foodborne toxins may cause allergic or anaphylactoidlike manifestations,⁸⁵ also sometimes referred to as “restaurant syndromes”¹⁴⁹ (Table 44–6). The similarity of these syndromes complicates a patient’s future approach to safe eating. Isolating the precipitant is essential so that the risk can be effectively assessed. Manufacturers of processed foods should provide an unambiguous listing of ingredients on package labels. Sensitive individuals (or in the cases of children their parents) must be rigorously attentive.^{141,180} Those who experience severe reactions should make sure that epinephrine and antihistamines are always available immediately. Attempts to prevent allergic reactions to dairy products by avoiding dairy-containing foods may fail. Nondairy foods may still be processed in equipment used for dairy products or contain flavor enhancers of a dairy origin (eg, partially hydrolyzed sodium caseinate), both of which can cause morbidity and death in allergic individuals.⁶¹ Individuals with known food allergies do not always carry prescribed autoinjectable spring-injected epinephrine syringes, in some cases from a belief that the allergen is easily identifiable and avoidable.⁸⁵ Food additives that can cause anaphylaxis include antibiotics, aspartame, butylated hydroxyanisole, butylated hydroxytoluene, nitrates or nitrites, sulfites, and paraben esters.¹⁰² Regulation of these preservatives is limited, and xenobiotics such as sulfites are so ubiquitous that predicting which guacamole, cider, vinegar, fresh or dried fruits, wines, or beers contain these sensitizing agents may be impossible.

TABLE 44–6. Epidemiologic Analysis of Gastrointestinal Disease

	Onset	Symptoms/Signs	Cause	Therapy
Anaphylaxis (anaphylactoid)	Minutes to hours	Urticaria, angioedema, bronchospasm, hypotension	Allergens—nuts, eggs, milk, fish, shellfish, peanuts, soy	Oxygen, epinephrine, β_2 -adrenergic agonist, corticosteroids, volume expansion, H_1 , H_2 histamine blockers, avoidance
Monosodium glutamate (MSG)	Minutes	Flushing, hypotension, palpitations, facial pressure, headaches, rhinitis, bronchospasm, shivering	Flavor enhancer of foods	Oxygen, β_2 -adrenergic agonists, volume expansion, avoidance
Metabisulfites	Minutes	Flushing, hypotension, bronchospasm	Preservative in wines, salad (bars), fruit juice, shrimp	See Anaphylaxis, avoidance
Scombroid	Minutes to hours	Flushing, hypotension, urticaria, headache, pruritis, gastrointestinal symptoms	Large fish—poorly refrigerated: tuna, bonito, albacore, mackerel, mahi mahi (histamine)	H_1 , H_2 blockers, supportive care, avoidance
Tyramine	Minutes to hours	Headache, hypertension (INH or MAOI) increases risk	Wines, aged cheeses	Avoidance for those with hypertension, migraines
Tartrazine	Hours	Urticaria, angioedema, bronchospasm	Yellow coloring food additive	See Anaphylaxis, avoidance

INH = isoniazid; MAOI = monoamine oxidase inhibitor.

Scombroid Poisoning

Scombroid poisoning originally was described with the Scombroideae fish (including the large dark-meat marine tuna, albacore, bonito, mackerel, and skipjack). However, the most commonly ingested vectors identified by the CDC are nonscombroid fish, such as mahi mahi and amber jack.³³ All of the implicated fish species live in temperate or tropical waters. Ingestion of bluefish in New Hampshire was the probable cause of scombroid poisoning in five people,⁵² and in a large outbreak, tuna was the offender in 71 cases reported from a military outpost.⁴⁷ The incidence of this disease is

probably far greater than was originally perceived. This type of poisoning differs from other fishborne causes of illness in that it is entirely preventable if the fish is properly stored following removal from the water.

Scombroid poisoning results from eating cooked, smoked, canned, or raw fish. The implicated fish all have a high concentration of histidine in their dark meat. *Morganella morganii*, *E. coli*, and *Klebsiella pneumoniae*, commonly found on the surface of the fish, contain a histidine decarboxylase enzyme that acts on a warm (not refrigerated), freshly killed fish, converting histidine to histamine, saurine, and other heat-stable substances. Although saurine has been suggested as the causative toxin, chromatographic analysis demonstrates that histamine is found as histamine phosphate and saurine is merely histamine hydrochloride.^{56,117} The term saurine originated from saury, a Japanese dried fish delicacy often associated with scombroid poisoning. The extent of spoilage usually correlates with histamine concentrations. Histamine concentrations in healthy fish are less than 0.1 mg/100 g fish meat. In fish left at room temperature, the concentration rapidly increases, reaching toxic concentrations of 100 mg/100 g fish within 12 hours.

The appearance, taste, and smell of the fish are usually unremarkable.⁵ Rarely, the skin has an abnormal “honeycombing” character or a pungent, peppery taste that may be a clue to its toxicity. Within minutes to hours after eating the fish, the individual experiences numbness, tingling, or a burning sensation of the mouth, dysphagia, headache, and, of particular significance for scombroid poisoning, a unique flush characterized by an intense diffuse erythema of the face, neck, and upper torso.⁸⁶ Rarely, pruritus, urticaria, angioedema, or bronchospasm ensues. Nausea, vomiting, dizziness, palpitations, abdominal pain, diarrhea, and prostration may develop.^{43,63,86,113}

The prognosis is good with appropriate supportive care and parenteral antihistamines such as diphenhydramine. H₂-receptor antagonists such as cimetidine or ranitidine may also be useful in alleviating gastrointestinal symptoms.¹⁸ The toxic substance should be removed or absorbed from the gut. Inhaled β_2 -adrenergic agonists and epinephrine may be necessary if bronchospasm is prominent. Patients usually show significant improvement within a few hours.

Elevated serum or urine histamine concentrations can confirm the diagnosis, but are usually unnecessary. If any uncooked fish remains, isolation of causative bacteria from the flesh is suggestive, but not diagnostic. A capillary electrophoretic assay makes rapid histamine detection possible.⁷⁹ Histamine concentrations greater than 50 mg/100 g fish meat are considered hazardous by the FDA; in Europe the concentrations are 100 to 200 mg/100 g.⁷⁹ Isoniazid may increase the severity of the reaction to scombroid fish by inhibiting enzymes that break down histamine.^{78,168}

Patients may be reassured that they are not allergic to fish if other individuals experience a similar reaction to eating the same fish at the same time, or if any remaining fish can be preserved and tested for elevated histamine concentrations. If this information is not available, then an anaphylactic reaction to the fish must be considered. Table 44–6 lists the differential diagnosis of flushing, bronchospasm, and headache. Because many people often consume alcohol with fish, alcohol must be considered an independent variable.

The differential diagnosis of the scombrototoxic flush apart from a disulfiramlike reaction includes ingestion of niacin or nicotinic acid, and pheochromocytoma. The history and clinical evolution usually establish the diagnosis quickly.

Global Food Distribution, Illegal Food Additives

Xenobiotics are given to animals to increase their health and growth. Clenbuterol, a β_2 agonist, has been administered to cattle raised for human consumption. The substance can cause toxicity in humans who eat contaminated animal meat. Tachycardia, tremors, nausea, epigastric pain, headache, muscle pain, and diarrhea were present in 50 poisoned patients. Other findings included hypertension and leukocytosis.¹³⁶ No deaths have been reported. The use of antibiotics, β_2 agonists, and other growth enhancers continues, despite safety concerns and laws against their use, because these practices increase yield and profit.

The globalization of food supplies and international agricultural trade has created a new global threat, the apparent purposeful contamination of food for profit. In 2008, almost 300,000 children in China were affected by melamine contamination of milk. Of these, 50,000 were hospitalized and 6 reported deaths occurred.

The melamine-contaminated milk was sold in China as powdered infant formula, with more than 22 brands containing melamine. The contamination was not limited to China, as melamine has been found in candy, chocolate, cookies, and biscuits sold in the United States, likely due to the adulteration of milk used in preparation of these products.

Melamine is a non-nutritious, nitrogen-containing compound, usually used in glues, plastics, and fertilizers. To increase profits, milk sold in China had previously been diluted, causing protein malnutrition in children. Because the nitrogen content of milk (a surrogate measure for protein content) is now carefully monitored to detect dilution and to prevent another episode of malnutrition, melamine was added to increase the measured nitrogen content and hide the dilution. This purposeful addition of melamine is suspected to be the cause of the melamine contamination of powdered milk in China.

Melamine and its metabolite cyanuric acid are excreted in the kidneys. Kidney stones containing melamine and uric acid were found in 13 children with acute kidney injury, who had consumed melamine containing milk formula.⁶⁹ Both melamine and cyanuric acid appear necessary to cause kidney stones in animals. The combination alone caused renal

crystals in cats.¹³⁵ Melamine found in wheat gluten was added to pet food in 2007 resulted in thousands of complaints, and dozens of suspected animal deaths in the United States.

The melamine milk contamination is one of the largest reported deliberate food adulteration incidents. It affected about 300,000 Chinese infants and young children and caused six deaths.^{41,80}

Food products from all over the world find their way into our foods. Increased vigilance by the agencies responsible for food safety, both in countries where the food originates and in countries that import the food, is needed to prevent other events such as the melamine contaminations.

Vegetables and Plants

Plants, vegetables, and their diverse presentations often are involved in food poisonings.^{72,87,88,93,94} Edible plants and plant products may be poorly cooked or prepared, or they may be contaminated. Extensive discussion of this may be found in Chap. 121.

FOOD POISONING AND BIOTERRORISM

The threat of terrorist assaults has received increased attention and is discussed in Chaps. 132 and 133. The use of food as a vehicle for intentional contamination with the intent of causing mass suffering or death has already occurred in the United States.^{38,90,165} In the first report, 12 laboratory workers had GI symptoms, primarily severe diarrhea, after consuming food purposefully contaminated with *Shigella dysenteriae* type II served in a staff break room.⁹⁰ Four workers were hospitalized; none had reported long-term sequelae. This *Shigella* strain rarely causes endemic disease. Nevertheless an identical strain, identified by pulsed-field gel electrophoresis, was found in eight of the 12 symptomatic workers, as well as in the pastries served in the break room, and in the laboratory stock culture of *S. dysenteriae*. This finding suggests purposeful poisoning of food eaten by laboratory personnel. The person responsible and the motive remain unknown.

The second case series describes a large community outbreak of food poisoning caused by *Salmonella typhimurium*.¹⁶⁵ The outbreak occurred in the Dalles, Oregon, area during the fall of 1984; a total of 751 people suffered salmonella gastroenteritis. The outbreak was traced to the intentional contamination of restaurant salad bars and coffee creamer by members of a religious commune using a culture of *S. typhimurium* purchased before the outbreak of food poisoning. A criminal investigation found a *Salmonella* culture on the religious commune grounds that contained *S. typhimurium* identical to the salmonella strain found in the food poisoning victims. It was identified by using antibiotic sensitivity, biochemical testing, and DNA restriction endonuclease digestion of plasmid DNA. Only after more than one year of investigation was this salmonella outbreak linked to terrorist activity. Reasons for the delay in identifying the outbreak as a purposeful food poisoning included (1) no apparent motive, (2) no claim of responsibility, (3) no pattern of unusual behavior in the restaurants, (4) no disgruntled restaurant employees identified, (5) multiple time points for contamination indicated by epidemic exposure curves, suggesting a sustained source of contamination and not a single act, (6) no previous event of similar nature as a reference, (7) the likeliness of other possibilities (eg, repeated unintentional contamination by restaurant workers), and (8) fear that the publicity necessary to aid the investigation might generate copycat criminal activity.

Publication of the event was delayed by almost 10 years out of fear of unintentionally encouraging copycat activity. On the other hand, use of biological weapons by the Japanese cult Aum Shinrikyo appears to have motivated authorities to release this publication in the hopes of quickly identifying similar deliberate food poisoning patterns in the future.

A third report describes a disgruntled employee who contaminated 200 lb of meat at a supermarket with a nicotine-containing insecticide.³⁸ Ninety-two people became ill, and four sought medical care. Symptoms included vomiting, abdominal pain, rectal bleeding, and one case of atrial tachycardia.

In another case of human greed, a Chinese restaurant owner poisoned the food in his neighbor's restaurant with tetramine. Tetramine or tetramethylenedisulfotetramine is a highly lethal neurotoxic rodenticide, once used worldwide, now illegal in the United States. The snack shop owner caused hundreds to become ill and 38 deaths by spiking his competitors' breakfast offerings (fried dough sticks, sesame cakes, and sticky rice balls). Tetramethylenedisulfotetramine is an odorless and tasteless white crystal that is water-soluble. The mechanism of action is noncompetitive irreversible binding to the chloride channel on the γ -aminobutyric acid receptor complex, which blocks the influx of chloride and alters the neurons' potential. It is referred to as a "cage convulsant" because of its globular structure. Severe toxicity presents with tachycardia, dysrhythmias, agitation as well as status epilepticus and coma. Immediate or early treatment with sodium-(RS)-2,3-dimercaptopropane-1-sulfonate (DMPS) and pyridoxine (vitamin B6) appears to be effective in a mouse model.^{12,50,174}

The capacity of foodborne xenobiotics that are easy to obtain and disburse to infect large numbers of people is clearly exemplified by two specific outbreaks: (1) the purposeful salmonella outbreak in Oregon, (2) the apparently unintentional salmonella outbreak that resulted in more than 16,000 culture-proven cases traced to contamination in an Illinois dairy. The probable cause of the outbreak was a contaminated transfer pipe connecting the raw and pasteurized milk containment tanks.¹³⁹ These events emphasize the vulnerability of our food supply and the importance of ensuring its safety and security.

SUMMARY

- The diverse etiologies of food poisoning involve almost all aspects of toxicology.
- Our concerns center around the natural toxicity of plants or animals, the contamination of which can occur in the field, during factory processing, subsequent transport and distribution, or during home preparation or storage.
- Whether these events are intentional or unintentional, they alter our approaches to general nutrition and society.
- Issues in food safety include the governmental role in food preparation and protection, bacteria such as *Salmonella* and *E. coli* O157:H7, prions in Creutzfeldt-Jacob disease (bovine encephalopathy), and genetically altered materials such as corn.
- Future discussions of food poisonings and interpretations of the importance of these problems may dramatically alter our food sources and their preparation and monitoring.

45 HERBAL PREPARATIONS

Oliver L. Hung

Although there is increased awareness of the widespread use of herbal preparations in the United States, physicians frequently seek information about their usage only after the patient demonstrates toxicity.

HISTORY AND EPIDEMIOLOGY

Since ancient times and perhaps since prehistoric times, people of all cultures have used herbal preparations to treat disease and promote health.⁴⁰ A 60,000 year-old Iraqi burial site contained eight different medicinal plants, suggesting very early historical usage.¹⁴² The earliest surviving written account of medicinal plants is the Egyptian Ebers papyrus, circa 1500 B.C., which lists dozens of medicinal plants and their intended uses. In India, the Vedas, epic poems written in approximately 1500 B.C., contain references to herbal preparations of the time. In China, the Divine Husbandman's Classic, written in the first century A.D., lists 252 herbal preparations. In ancient Europe, herbal medicines were the mainstay of healing. In the first century, the Greek physician Dioscorides wrote one of the first European herbal books, *De Materia Medica*, which listed 600 herbals and was translated into many languages. Shamans and folk healers from the Americas, Africa, Australia, and Asia continue to include herbals for spiritual and medicinal purposes based on oral traditions passed from generation to generation.

During the Scientific Revolution, European scientists began to isolate purified extracts of plant products for use as medicinal agents. In 1804 and 1832, morphine and codeine were isolated from the sap of the poppy plant *Papaver somniferum*.⁷³ In the mid-eighteenth century, Edward Stone described in a letter to the president of the Royal Society of Medicine the successful use of the bark of the willow tree in curing "agues" (fever).²⁰ In 1829, salicin, the active ingredient of the willow bark, was identified. Its derivative sodium salicylate was marketed in 1875 as a treatment for rheumatic fever and as an antipyretic. The enormous success of this drug led to the synthesis of acetylsalicylic acid in 1899. The original name, aspirin (acetyl-spiric acid), is said to have been derived from *Spiraea*, the plant genus from which salicylic acid once was prepared. Even today, plant preparations still are being investigated for the development of modern drugs. Sweet wormwood (*Artemisia annua*, qing hao) was first described as a treatment for malaria in China in 168 B.C.⁸⁸ In 1971, the active parent compound artemisinin was first isolated by Chinese investigators. Artemisinin, when used in combination with other antimalarials, is considered the best treatment for falciparum-resistant malaria.^{85,107,134} Prescriptions from plant-derived medicines currently represent approximately 25% of prescriptions dispensed in the United States^{2,163} and at least 60% of nonprescription medications contain one or more natural products as ingredients.⁴⁸

Herbal preparations continue to be the dominant form of healing in the developing world because of the high cost of "Western" medical treatment and the scarcity of "Western"-trained medical personnel.^{47,92,95,108} The World Health Organization estimates that 4 billion people, up to 80% of the world population, use herbal preparations for some aspect of primary health care.^{2,166}

Herbal preparations and other dietary supplements are not only sold exclusively in health food stores but are readily available for sale in mainstream retail outlets such as grocery stores, drug stores, complementary medicine practitioners, offices, mail order companies, the Internet, and gasoline stations. US pharmaceutical companies have also entered the herbal market. US herbal dietary supplement sales were estimated at \$5.3 billion in 2011, representing direct sales of \$2.6 billion, natural and health food sales of \$1.8 billion, and \$1 billion from mass-market retailers. Over the last 4 years, sales have continued to increase: 4.5% in 2011, 0.2% increase in 2010, 4.8% in 2009, and 0.9% in 2008.¹⁴ Similarly, worldwide herbal preparation usage continues to grow. The current global herbal supplements and remedies market is valued at \$62 billion and it is predicted to reach \$107 billion by 2017.⁶⁷

Although they often are used by consumers in the hope of preventing or treating medical illness, herbals are not classified as medications; therefore, despite reports of toxicity associated with their usage, no systematic evaluation of herbal efficacy or safety is required. Additionally problematic is that patients often do not consider herbal preparations as medications and may not provide a history of usage unless questioned specifically about herbal usage.

Unfortunately, the medical profession's response to the widespread usage of herbal preparations appears to be inconsistent, with one study suggesting that the medical practitioner's knowledge of current herbal preparation regulations

is grossly inadequate.⁶ Several studies have attempted to determine how US hospitals regulate herbal preparation use in their facilities.^{4,9,43,63} Depending on the study, only 31% to 79% of respondents reported having formal policies governing the usage of herbal preparations in their facilities. Herbal preparation use was completely banned in 11% to 22% of facilities. However, the majority of facilities did allow the use of herbal preparations if they were ordered by an authorized prescriber. Identified concerns addressed in these studies included difficulties in identifying products (particularly “home supply” products), and concerns for appropriate dosing, efficacy, safety, and consistency. The conflicting approaches have been attributed to health care facilities attempting to balance patient-centered care with their legal, medical, and ethical concerns about these products.^{17,63}

In 1998, Congress established the National Center for Complementary and Alternative Medicine (NCCAM) at the National Institutes of Health to stimulate, develop, and support research in complementary and alternative medicines.¹⁰⁵ So far, NCCAM-funded studies have failed to demonstrate any clinical benefit for using St. John’s wort for depression,⁸¹ hawthorne for congestive heart failure,¹⁷⁰ echinacea for the common cold,¹⁵² glucosamine and chondroitin sulfate for osteoarthritis,⁴² saw palmetto for benign prostatic hypertrophy,¹¹ Ginkgo biloba for dementia,⁵² shark cartilage for lung cancer,¹⁰⁰ and cranberry juice for recurrent urinary tract infections.⁴¹

DEFINITION

The botanical definition of the term herb is specific for certain leafy plants without woody stems. However, the term herbal preparations often includes non-herb plant materials, even animal and mineral products. Thus, in a broad sense, the term herbals includes any “natural” or “traditional” remedy, but these terms also are poorly defined. Although these xenobiotics are often also called medications, this terminology may be inaccurate and misleading. Many herbal preparations purportedly are used for their nonspecific “adaptogenic” properties by permitting the body to return to a normal state by resisting stress, but they lack any specific medicinal effects. Because many herbal users and herbalists do not consider herbal preparations medications, use of the term herbal medicine by the clinician may convey a different, and perhaps unintended, meaning. For these reasons, it may be inappropriate and without benefit to refer to these products as medication, but they are xenobiotics.

Herbal preparations are considered to be a subset of “alternative therapies.” These therapies are defined as interventions that are neither widely taught in US medical schools nor generally available in US hospitals.⁵⁴ When these alternative therapies are used in conjunction with conventional medical therapies, they are also known as complementary and alternative medicine (CAM).¹¹⁷ The NCCAM groups CAM into five domains: whole medical systems (eg, Ayurveda, homeopathy), mind–body medicine (eg, prayer, hypnosis), biologically based practices (eg, herbal preparations, dietary supplements), manipulative and body-based practices (eg, acupressure, acupuncture, chiropractic, massage), and energy medicine (eg, therapeutic touch).¹¹⁷

The study of herbal preparations is complicated by the lack of standardized nomenclature, while the diversity of common, proprietary, and botanical names may increase the confusion. A single plant preparation may have many common names, in addition to its botanical name. For example, *Datura stramonium* is also known as jimson weed, Angel’s trumpet, apple of Peru, Jamestown weed, thornapple, and tolguacha. Likewise, a common name for a plant, such as gordolobo, may refer to several plants, such as *Verbascum thapsus* and *Gnaphalium macounii*.⁸⁰ The mandrake refers not only to the belladonna-alkaloid-containing *Mandragora officinarum* but also the podophyllum-containing *Podophyllum peltatum*. Thus, accurate classification of herbal preparations is very difficult, which limits effective study and increases the risk of adverse effects.

REGULATION OF HERBAL PREPARATIONS

For regulatory purposes the US government classifies herbal preparations as a type of dietary supplement, which means that the US Food and Drug Administration (FDA) classifies them as nutrients with nondrug status.⁴⁵ However, many nonherbals, such as vitamins, minerals, nutritional supplements, and food additives, are also dietary supplements (Chaps. 42, 46, and 47).

In the United States, herbal preparations are not subjected to the same standards as drugs. The FDA has gradually assumed an increased role in its vigilance over the manufacturing, marketing, and sales of herbal preparations. In 1994, Congress passed the Dietary Supplement Health and Education Act, which reduced the oversight by the FDA of products categorized as dietary supplements.⁵⁷ Dietary supplements include vitamins, minerals, herbals, amino acids, and any product that had been sold as a “supplement” before October 15, 1994.⁴⁵ After October 15, 1994, any new ingredient intended for use in dietary supplements requires notification and approval by the FDA at least 75 days in advance of marketing. The FDA must review and determine whether the proposed ingredient is expected to be safe under the intended conditions for use. However, because most ingredients contained in dietary supplements were in use prior to 1994, the vast majority of dietary supplements are not subject to even this weakened premarket safety evaluation. After marketing, if the

FDA determines that a manufactured dietary supplement is unsafe, the agency can warn the public, suggest changes to make the supplement safer, urge the manufacturer to recall the product, recall the product, or ban the product.

On several occasions the FDA has urged manufacturers to stop producing dietary supplements containing unsafe products. In July 2001, the FDA warned dietary supplement manufacturers to stop marketing products containing aristolochic acid because of nephrotoxicity and to remove comfrey products from the market because of hepatotoxicity. In November 2001, the FDA warned the manufacturer of LipoKinetix (containing phenylpropanolamine, caffeine, yohimbine, diiodothyronine, usnic acid) to remove the supplement from the marketplace because of reports of associated hepatotoxicity. In 2002, the FDA warned consumers and health care professionals of the risk of hepatotoxicity associated with the use of kava-containing products.¹⁵⁷ However, the FDA did not ban the development of kava-containing products or ban their sale in the United States. In March 2004, the FDA warned dietary supplement manufacturers to stop manufacturing androstenedione or face enforcement actions.¹⁵⁶ To ban a dietary supplement from the marketplace, the FDA must prove that the product is unsafe. In April 2004, the FDA banned all sales of dietary supplements containing ephedra. This was the first FDA prohibition of a supplement since 1994.¹⁵⁵ In April 2012, FDA warned manufacturers that the stimulant used in some fitness supplements, dimethylamylamine, did not qualify as a legal dietary supplement. One year later, the FDA issued a consumer warning that dimethylamylamine usage is associated with cardiovascular complications with 86 reported illnesses and deaths.¹⁵⁸

Because the law requires the FDA to consider dietary supplements as food products, quality control issues and production methods are governed by the Current Good Manufacturing Practices regulations for foods.¹⁵⁴ However, these regulations only ensure that foods, and thus dietary supplements, are produced under sanitary conditions; they do not guarantee the safety, efficacy, or quality of the product, as is required for pharmaceuticals. Two studies suggest that many herbal preparations do not even contain appreciable quantities of the listed herb. In one study of 54 ginseng products, 60% of those analyzed contained pharmacologically insignificant amounts of ginseng and 25% contained no ginsenosides.⁹⁷ A study of echinacea preparations determined that 10% of preparations contained no measurable echinacea, the assayed species was consistent with labeled content in 52% of the sample, and only 43% met the quality standard described by the label.⁶⁵ From 2004 to 2008, the FDA investigated online sales of dietary supplements purported to treat erectile dysfunction or enhance sexual performance by purchasing and analyzing the ingredients of these products.¹⁵³ One-third of the purchased dietary supplements (six out of 17) contained undisclosed prescription drug ingredients such as sildenafil, vardenafil, or related substances.¹⁵³ In a 2010 press announcement, the FDA revealed that the three most common categories of tainted products marketed as dietary supplements are weight loss products containing active ingredients such as sibutramine, body-building products containing anabolic steroids or steroid analogs, and sexual enhancement products that contain phosphodiesterase type 5 inhibitors such as sildenafil.⁵⁹

Herbal products can be initially marketed without any proof of testing for efficacy or safety. Although packaging that claims to cure or prevent a specific disease is not permitted unless approved by the FDA, claims detailing how a product affects the “body’s structure or function” are permissible. Substantiation of these claims is required only if challenged by regulators,¹⁵⁴ but the methodology and requirements for this substantiation are not well defined.

These findings were corroborated by a study evaluating herbal advertising on the Internet. The study determined that 81% of Web sites marketing dietary supplements made one or more health claims without approval from the FDA, and of these sites, 55% made specific claim to treat, prevent, or cure a specific disease.¹¹³

In March 1999, the FDA implemented new dietary supplement labeling rules. All dietary supplement labels must provide a statement of identity (eg, ginseng), net quantity of contents (eg, 60 capsules), structure–function claims with disclaimers that the product has not been evaluated by the FDA; directions for use; supplements fact panel (list of serving size, amount, and active ingredients), other ingredients list, and name and place of business of manufacturer, packer, or distributor. The Dietary Supplement and Nonprescription Drug Consumer Protection Act was signed into law in December 2006.⁵¹ Under this law, manufacturers, packers, or distributors of nutritional supplements are required to notify the FDA about serious adverse events related to their products. In 2007, the FDA issued its current good manufacturing practices final rule, effective in June 2008. The final rule is more stringent than previous regulations and it contains sections similar to current good manufacturing practices for drugs. Manufacturers are required to evaluate the identity, purity, strength, and composition of their dietary supplements. Yet, unlike the FDA regulations for drugs, the final rule still does not require any proof of efficacy or safety. In essence, the FDA, through its regulations, has gradually shifted dietary supplements from a poorly regulated food product into a unique category between a conventional food product and a drug. This has served to fuel the debate on both sides: those who view dietary supplements as more similar to food groups (eg, chamomile tea) and want less government regulation, and others who argue that herbs contain pharmacologically active drugs (eg, ephedra) that require greater regulation.^{106,114}

The FDA recently released data suggesting that its regulations alone are insufficient in ensuring the safety of dietary supplements sold in the United States. Since it began assessing good manufacturing practice compliance in 2008, the FDA has found violations of manufacturing rules in nearly one-half of the 450 dietary supplement firms it has inspected. One in four inspected companies had violations serious enough to warrant release of an FDA warning letter that could result in a

significant enforcement action such as halting production and distribution. The FDA also believes that adverse events associated with dietary supplements are significantly underreported by manufacturers even though it is required by law. For the first 10 months of 2008, the FDA received approximately 950 reports of adverse events, but the agency estimates the true annual number of adverse events is much higher at 50,000.^{102,151} In 2009, the US Government Accountability Office issued a report to Congress that provided four recommendations highlighting the difficulties the FDA had in ensuring the safety of dietary supplements sold in the United States.¹⁵⁹ First, the FDA should be given the authority to require dietary supplement companies to identify themselves as a dietary supplement company, to provide a list of all dietary supplement products they sell, and to report all adverse events related to dietary supplements. Second, the FDA should issue guidance to clarify when an ingredient is considered a new dietary ingredient, the evidence needed to document the safety of a new dietary ingredient, and appropriate methods to establish ingredient identity. Third, the FDA should provide guidance to the industry to clarify when products should be marketed as either dietary supplements or conventional food formulated with added dietary ingredients. Fourth, the FDA should coordinate with consumer outreach to educate consumers about the safety and efficacy of dietary supplements and to assess the effectiveness in improving consumer understanding about dietary supplement. In 2010, the US Government Accountability Office also conducted an investigation to determine whether storefront and mail-order retailers of herbal preparations are using deceptive or questionable marketing practices and whether herbal dietary supplements are contaminated with harmful substances.¹⁶⁰ The investigation found that many herbal dietary supplement retailers were making improper health claims and in some cases were giving potentially harmful medical advice. The study also found that many herbal dietary supplements contain contaminants. In 37 of the 40 herbal dietary supplements tested, trace contaminants were identified (metals or pesticides), although none were identified in quantities considered to be acutely toxic.

PHARMACOLOGIC PRINCIPLES

The pharmacologic activity of herbal preparations (plant containing or derived) can be classified by five active constituent classes: volatile oils, resins, alkaloids, glycosides, and fixed oils.¹⁴⁴

- **Volatile oils** are aromatic plant ingredients. They are also called ethereal or essential oils, because they evaporate at room temperatures. Many are mucous membrane irritants and have central nervous system (CNS) activity. Examples of herbs containing volatile oils include pennyroyal oil (*Mentha pulegium*), catnip (*Nepeta cataria*), chamomile (*Chamomilla recutita*), and garlic (*Allium sativum*; Chap. 43).
- **Resins** are complex chemical mixtures of acrid resins, resin alcohols, resinol, tannols, esters, and resenes. These substances are often strong gastrointestinal (GI) irritants. Examples of resin-containing herbs include dandelion (*Taraxacum officinale*), elder (*Sambucus* spp), and black cohosh root (*Cimicifuga racemosa*).
- **Alkaloids** are a heterogeneous group of alkaline and nitrogenous compounds. The alkaloid compound usually is found throughout the plant. This class consists of many pharmacologically active and toxic compounds. Examples of alkaloid-containing herbs include aconitum (*Aconitum napellus*), goldenseal (*Hydrastis canadensis*), and Jimson weed (*Datura stramonium*).
- **Glycosides** are esters that contain a sugar component (glycol) and a nonsugar (aglycone), which yields one or more sugars during hydrolysis. They include the anthraquinones, saponins, cyanogenic glycosides, and lactone glycosides. The anthraquinones (senna {*Cassia acutifolia*} and aloe {*Aloe vera*}) are irritant cathartics. Saponins (licorice {*Glycyrrhiza lepidota*} and ginseng {*Panax ginseng* and *P. quinquefolius*}) are mucous membrane irritants, cause hemolysis, and have steroid activity. Cyanogenic glycosides found in apricot, cherry, and peach pits release cyanide. Lactone glycosides (tonka beans {*Dipteryx odorata*}) have anticoagulant activities. Cardiac glycosides defined as cardioactive steroids (Chap. 65) are found in foxglove (*Digitalis* spp) and oleander (*Nerium oleander*).
- **Fixed oils** are esters of long-chain fatty acids and alcohols. Herbs containing fixed oils are generally used as emollients, demulcents, and bases for other products. Generally, they are the least active and least dangerous of all herbal preparations. Examples include olive (*Olea europaea*) and peanut (*Arachis hypogaea*) oils.

Factors Contributing to Herbal Toxicity

The toxicity of a plant may vary widely and depends on conditions such as the time of year and developmental stage at which the plant is collected.⁸⁰ The pyrrolizidine alkaloid content of *Senecio* leaves varies widely from month to month and year to year.⁸⁰ In some cases, only selective parts of a plant used to prepare an herbal preparation are responsible for its toxicity. For example, the pyrrolizidine content of comfrey–pepsin capsules varies from 270 to 2900 mg/kg, depending on whether the leaves or roots were used in the preparation.⁷⁹ The geographical area in which the plant is collected may affect its toxicity. *Senecio longilobus* from Gardner Canyon, Arizona, may contain up to 18% pyrrolizidine alkaloids by dry weight, the highest concentration/amount recorded for any *Senecio* plant species (normal concentration is 0.5%). Finally, conditions and duration of storage may affect its toxicity. The toxicity of *Crotalaria* decreases with storage because of the breakdown of pyrrolizidines.

Few poisonings result from the inherent toxicity of the herbal, because of the low concentration of active ingredient and the known safety of the chosen herb (Table 45–1). Instead, poisonings tend to result from the misuse, overuse (including increased concentration in some commercial derivative products), misidentification, misrepresentation, or contamination of the product. Metal and mineral poisonings from lead, cadmium, mercury, copper, selenium, zinc, and arsenic are associated with herbal preparation usage.^{28,36,46,50,53,121,125,130} High concentrations of these salts sometimes result from contamination during the manufacturing process of some herbal or patent medications (ready-made preparations used by traditional Chinese herbalists). In some cases, as with cinnabar (mercuric sulfide) and calomel (mercurous chloride), these ingredients are intentionally included for purported medicinal benefit.⁸⁶ Patent medications may also contain pharmaceutical medications, such as acetaminophen, aspirin, antihistamines, or corticosteroids.^{37,50} Many of these medicines are not listed on the packaging and may not even be approved for use in the United States. For example, four cases of agranulocytosis followed consumption of Chui Fong Tou Ku Wan, a preparation that contains both aminopyrine (which is not approved for nonprescription sales in the United States) and phenylbutazone (which was withdrawn from the US market in the 1980s), neither of which are listed on the packaging.¹³² Both aminopyrine and phenylbutazone are associated with agranulocytosis.

TABLE 45–1. Laboratory Analysis and Treatment Guidelines for Specific Herbal Preparations

<i>Herbal Preparation</i>	<i>Suggested Laboratory Analysis</i>	<i>Antidote</i>
Cardiac xenobiotics		
Ch'an Su (Bufo Bufo)	Serum digoxin, potassium	Digoxin-specific Fab
Foxglove	Serum digoxin, potassium	Digoxin-specific Fab
Oleander	Serum digoxin, potassium	Digoxin-specific Fab
Squill	Serum digoxin, potassium	Digoxin-specific Fab
Central nervous system xenobiotics		
Henbane	None	Physostigmine
Jimson weed (Datura)	None	Physostigmine
Mandrake	None	Physostigmine
Gastrointestinal xenobiotics		
Aloe	Serum electrolytes	Potassium repletion
Buckthorn	Serum electrolytes	Potassium repletion
Cascara	Serum electrolytes	Potassium repletion
Fo-Ti	Serum electrolytes	Potassium repletion
Senna	Serum electrolytes	Potassium repletion
Hematologic xenobiotics		
Dong Quai	PT	Vitamin K ₁
Tonka bean	PT	Vitamin K ₁
Woodruff	PT	Vitamin K ₁
Hepatic xenobiotics		
Pennyroyal oil	AST/ALT	N-acetylcysteine
Pyrrolizidine alkaloids	AST/ALT	None available
Metals		
	Ag, As, Au, Cd, Cr, Cu, Hg, Pb, Th, or Zn	Metal chelators
	Abdominal radiograph (as appropriate)	
Salicylates		
Medicated oils	Serum salicylate	Sodium bicarbonate, multiple-dose activated charcoal, hemodialysis
Cellular xenobiotics		
Apricot pits (cyanogenic amygdalin)	Lactate	Cyanide antidote
	WBC, BUN	? Glutamic acid
Autumn crocus (colchicine)	Lactate	Cyanide antidote
	WBC, BUN	? Glutamic acid
Elder (cyanide)	WBC, BUN	? Glutamic acid
May apple (podophyllin)		
Periwinkle (vincristine)		
Miscellaneous		
Licorice	Serum potassium	Potassium repletion
Quinine	ECG, serum potassium	Sodium bicarbonate, magnesium

ALT = alanine transferase; AST = aspartate transferase; BUN = blood urea nitrogen; ECG = electrocardiography; PT = prothrombin time; WBC = white blood cell.

CLASSIFICATION OF TOXICITY

Herbal preparations are associated with a wide variety of toxicologic manifestations (Table 45–2). In addition, many

individual herbal preparations are associated with multiple toxicologic effects. To better understand these effects, it is useful to organize herbal toxicity into several general categories.⁵⁹

TABLE 45–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities

<i>Herbal Preparation</i>	<i>Scientific Name</i>	<i>Other Common Names</i>	<i>Traditional and Popular Usage</i>	<i>Active/Toxic Ingredient(s)</i>	<i>Adverse Events</i>
Aconite	<i>Aconitum napellus</i> <i>Aconitum kuznetsovii</i> <i>Aconitum carmichaelii</i>	Monkshood, wolfsbane caowu, chuamwu, bushi	Topical analgesic, neuralgia, asthma, heart disease	Aconite alkaloids (C19 diterpenoid esters) aconitine	GI upset, dysrhythmias
Agrimony	<i>Agrimonia eupatoria</i>	Cocklebur, stickwort, liverwort	Cataract, gallbladder disease, astringent		Photodermatitis
Alfalfa	<i>Medicago sativa</i>		Arthritis, diabetes	L-canavanine	High doses: lupus, pancytopenia
Aloe	<i>Aloe vera</i> and other spp	Cape, Zanzibar, Socotrine, Caracas, Carribyn	Heals wounds, emollient, laxative, abortifacient	Anthraquinones, barbaloin, isobarbaloin	GI upset, dermatitis, hepatitis
Apricot pits	<i>Prunus armeniaca</i>	—	(Laetrile) cancer remedy	Amygdalin	Cyanide poisoning
Aristolochia	<i>Aristolochia clematis</i> <i>Aristolochia reticulata</i> <i>Aristolochia fangchi</i>	Birthwort, heartwort, fangchi	Uterine stimulant, cancer treatment, antibacterial	Aristolochic acid	Nephrotoxin Renal cancer Retroperitoneal fibrosis
Artemisia	<i>Artemisia vulgaris</i> <i>Artemisia dracunculoides</i> <i>Artemisia lactiflora</i>	Mugwort, felon herb, moso, guzhou	Depression, dyspepsia, menstrual disorder, abortifacient	Lactones (sesquiterpenes)	GI upset, allergic reaction (skin, pulmonary)
Astragalus	<i>Astragalus membranaceus</i>	Huang qi, milk vetch root	Immune booster, AIDS, cancer, antioxidant, increase endurance	Astragalosides, trigonoside, and flavonoid constituent	May alter effectiveness of immunosuppressives (eg, steroids, cyclosporine)
Atractylis	<i>Atractylis gummifera</i>	Pinay thistle	Chewing gum, antipyretic, diuretic, gastrointestinal remedy	Potassium atractylate and gummiferin	Hepatitis, altered mental status, seizures, vomiting, hypoglycemia
Atractylodes	<i>Atractylodes macrophala</i>	Baizhu, cangzhu	Appetite stimulant, diuretic, GI upset	Atractylon, atractylol, atractylenolides	None
Autumn crocus	<i>Colchicum autumnale</i>	Crocus, fall crocus, meadow safran, mysteria, vellorita	Gout, rheumatism, prostate, hepatic disease, cancer, gonorrhea	Colchicine	GI upset, renal disease, agranulocytosis
Bee pollen, royal jelly	Derived from <i>Apis mellifera</i>	—	Increase stamina, athletic ability, longevity	Pollen mixture containing hyperallergenic plant pollen or fungi contamination	Allergic reactions, anaphylaxis
Bee venom	Derived from <i>Apis mellifera</i>	—	Immunomodulator	Phospholipase A2 and melittin, hyaluronidases	Allergic reactions, anaphylaxis
Betel nut	<i>Areca catechu</i>	Areca nut, pinlang, pinang	Stimulant	Arecoline	Possible bronchospasm, chronic use associated with leukoplakia and oropharyn- geal squamous cell carcinoma
Bilberry	<i>Vaccinium myrtillus</i>	Whortleberry, black whortles	Diarrhea, night vision, varicose veins	Anthocyanosides	None reported
Bitter orange	<i>Citrus auranti</i>	Changcao, Fructus auranti, green orange, kijiwa, Seville orange, sour orange, Zhi shi	Dyspepsia, increase appetite Weight loss	Synephrines	Cardiovascular toxicity, ephedrinelike effects
Bitter melon	<i>Momordica charantia</i>	Balsam pear	Abortifacient, diabetes, GI disorder, cancer, HIV therapy	Polysaccharide MAP-30 (protein)	None reported
Black cohosh	<i>Cimicifuga racemosa</i>	Black snakeroot, squawroot, bugbane, baneberry	Abortifacient, menstrual irregularity, astringent, dyspepsia	Triterpene glycosides	Dizziness, nausea, vomiting, headache
Black currant oil	<i>Ribes nigrum</i>	Quincy berry, squawcny berry	Immunostimulant, premen- strual syndrome	GLA (γ -linolenic acid) ALA (α -linolenic acid)	None reported
Blue cohosh	<i>Caulophyllum thalictroides</i>	Squaw root, papoose root, blue ginseng	Abortifacient, dysmenorrhea, antigastric	N-methylcytisine (2.5% the potency of nicotine)	Nicotinic toxicity

Boneset	<i>Eupatorium perfoliatum</i>	Thoroughwort, vegetable antimony, feverwort	Antipyretic	Pyrolizidine alkaloids	Possible hepatotoxicity, dermatitis, milk sickness
Borage	<i>Borago officinalis</i>	Beet plant, bee bread	Diuretic, antidepressant, antiinflammatory	Pyrolizidine alkaloids, amabiline	Hepatotoxicity
Boron		Boron	Topical astringent, wound remedy	Boron	Dermatitis, GI upset, renal and hepatic toxicity, seizures, coma, death
Broom	<i>Cytisus scoparius</i>	Scotch broom, Bannal, broom top	Cathartic, diuretic, induce labor, drug of abuse	L-Sparteine	Nicotinic toxicity
Buchu	<i>Agathosma betulina</i>	Bookoo, buku, diosma, buchu, bucco	Diuretic, stimulant, carminative, urine infections, insect repellent	Diosmin, hesperidin, pulegone	None reported
Buckthorn	<i>Rhamnus frangula</i>		Laxative	Anthraquinones	Diarrhea, weakness
Burdock root	<i>Artium lappa</i> <i>Artium minus</i>	Great burdock, gobo, lappa, beggar's button, harebur, niu bang zi	Diuretic, choleretic, induce sweating, skin disorders, burn remedy, diabetes treatment	Atropine (contamination with belladonna alkaloids during harvesting)	Anticholinergic toxicity
Calendula	<i>Calendula officinalis</i>	Marigold, garden marigold, pot marigold, gold blooms, hollygold	Wounds, dysmenorrhea, "radiation" dermatitis		None reported
Cantharidin	<i>Cantharis vesicatoria</i> beetle	Spanish fly, blister beetles	Aphrodisiac, abortifacient, blood purifier	Terpenoid: cantharidin	GI upset, urinary tract and skin irritant, renal toxicity
Caraway	<i>Umbelliferae carvi</i>		Antispasmodic, carminative	D-Carvone	
Carp bile (raw)	<i>Oreopharyngodon idella</i> <i>Cyprinus carpio</i>	Grass carp Common carp	Improve visual acuity and health	† Cyprinol, C27 bile alcohol	Hepatitis, renal failure
Cascara	<i>Rhamnus purshiana</i>	Cascara sagrada	Laxative	Anthraquinones	Diarrhea, weakness
Cat's claw	<i>Uncaria tomentosa</i> <i>Uncaria guianensis</i>	Uña de gato	AIDS, cancer, arthritis, ulcers, dysmenorrhea, wounds, contraceptives	Pentacyclic oxindole alkaloids, tetracyclic oxindole alkaloids	None reported
Catnip	<i>Nepeta cataria</i>	Catania, catnep, catmint	Indigestion, colic, sedative, euphoriant, headaches, emmenagogue	Nepetalactone	Sedative
Ch'an Su	<i>Bufo bufo garpinorum</i> <i>Bufo bufo melanostictus</i>	Stone, limestone, black stone, rock hard, chuan wu, kyeshin	Topical anesthetic, aphrodisiac, cardiac disease	Bufoadienolides, bufotenin	Dysrhythmias, hallucinations
Chamomile	<i>Matricaria inodora</i> , <i>Chamaemelum nobile</i>	Manzanilla	Digestive disorders, skin disorders, cramps	Allergens	Contact dermatitis, allergic reaction, anaphylaxis very rare
Chaparral	<i>Larrea tridentata</i>	Oreosote bush, greasewood, hediondilla	Bronchitis, analgesic, anti-aging, cancer	Homodihydroqualeic acid	Hepatotoxicity (chronic)
Chestnut	<i>Chestnut</i>	Horse chestnut, California buckeye, Ohio buckeye, buckeye	Arthritis, rheumatism, varicose veins, hemorrhoids	Esculetin, nicotine, quercetin, quercitrin, rutin, saponin, shikimic acid	Fasciculations, weakness, incoordination, GI upset, paralysis, stupor
Chuen-Lin	<i>Coptis chinensis</i> , <i>Coptis japonicum</i>	Golden thread, Huang-Lien, Ma-Huang	Infant tonic	Berberine: displaces bilirubin from protein	Neonatal hyperbilirubinemia
Clove	<i>Syzygium aromaticum</i>	Caryophyllum	Expectorant, antiemetic, counterirritant, anesthetic, carminative euphoriant	Eugenol (4-allyl-2-methoxyphenol)	Pulmonary toxicity (cigarettes)
Coltsfoot	<i>Tussilago farfara</i>	Coughwort, horsehood, koandong hua	Throat irritation, asthma, bronchitis, cough	Pyrolizidine alkaloids: tussilagin, senkirkine	Allergy, hepatotoxicity
Comfrey	<i>Symphytum officinale</i> , <i>Symphytum</i> spp., <i>S. x uplandicum</i>	Knitbone, bruisewort, black-wort, slippery root, Russian comfrey	Ulcers, hemorrhoids, bronchitis, burns, sprains, swelling, bruises	Pyrolizidine alkaloids: symphytine, echinidine, laurocarpine	Hepatic veno-occlusive disease

Compound Q	<i>Trichosanthes kirilowii</i>	Guaioogen, GLQ-223, Chinese cucumber root	Fever, swelling, expectorant, abortifacient, diabetes, AIDS	Trichosantin	Pulmonary injury (ALI), cerebral edema, cerebral hemorrhage, seizures, fever
Cordyceps (mushroom)	<i>Cordyceps sinensis</i>	Dong chong xia cao	Genital tonic, aphrodisiac, bronchitis, kidney disorders	Cordyceptic acid, Cordycepin	None reported
Damiana	<i>Turnera diffusa</i> var <i>aphrodisiaca</i>	—	Stimulant, purgative, aphrodisiac, antidepressant	Caryophyllene oxide, caryophyllene, δ -cadinene, elemene, 1,8-cineol	Genitourinary irritation
Dandelion	<i>Taraxacum officinale</i>		Diuretic, detoxifying remedy, bitter	Luteolin	None reported
Deer antler velvet			Erectile dysfunction, infertility, immunostimulant, antiinflammatory, athletic performance	Small amounts of androstenedione, dihydroepiandrosterone, and testosterone	None reported
Dong Quai	<i>Angelica polymorpha</i>	Tang kuei, dang gui	Blood purifier, dysmenorrhea, improve circulation	Coumarin, psoralens, safrole in essential oil	Anticoagulant effects, photodermatitis, possible carcinogen in oil
Echinacea	<i>Echinacea angustifolia</i> , <i>Echinacea purpurea</i>	American cone flower, purple cone flower, snakeroot	Infections, immunostimulant	Echinacoside	CYP1A2 inhibitor
Elder	<i>Sambucus</i> spp	Elderberry, sweet elder, sambucan	Diuretic, laxative, astringent, cancer	Isoquercitrin (cyanogenic glycoside: sambunigrin in leaves)	GI upset, weakness if uncooked leaves ingested
Ephedra	<i>Ephedra</i> spp	Ma-huang, Mormon tea, yellow horse, desert tea, squaw tea, sea grape	Stimulant, bronchospasm	Ephedrine, pseudoephedrine	Headache, insomnia, dizziness, palpitations, seizures, stroke, myocardial infarction, death
Evening primrose	<i>Oenothera biennis</i>	Oil of evening primrose	Coronary disease, multiple sclerosis, cancer, diabetes, rheumatoid arthritis, premenstrual syndrome	Cis- γ -linoleic acid	Lower seizure threshold
Fennel	<i>Foeniculum vulgare</i>	Common, sweet, or bitter fennel	Gastroenteritis, expectorant, emmenagogue, stimulate lactation	Volatile oils: transanethole, fenchone; estrogens: dianethole, photoanethole	Ingestion of volatile oils: vomiting, seizures, pulmonary injury (ALI), dermatitis, estrogen effects
Fenugreek	<i>Trigonella foenum-graecum</i>	Bird's foot, Greek hay seed	Expectorant, demulcent, antiinflammatory, emmenagogue, galactagogue, diabetes	4-hydroxyisoleucine	Hypoglycemia, hypokalemia
Feverfew	<i>Tanacetum parthenium</i>	Featherfew, altamisa, bachelor's button, featherfoil, febrifuge plant, midsummer daisy, nosebleed, wild quinine	Migraine headache, menstrual pain, asthma, dermatitis, arthritis, antipyretic, abortifacient		Oral ulcerations, "postfeverfew syndrome," rebound of migraine symptoms, anxiety, insomnia following cessation of chronic use
Fo-Ti	<i>Polygonum multiflorum</i>	Climbing knotwood, he shou-wu	Scrofula, cancer, constipation therapy, promote longevity	Anthraquinones: chrysophanol, emodin, rhein	Cathartic effects
Foxglove	<i>Digitalis purpurea</i> , <i>Digitalis lanata</i> , <i>Digitalis lutea</i> , <i>Digitalis</i> spp	Purple foxglove, throatwort, fairy finger, fairy cap, lady's thimble, scotch mercury, witch's bells, dead man's bells	Asthma, sedative, diuretic/ cardiotonic, wounds and burns (India)	Cardioactive steroids (eg, digitoxin, gitoxin, digoxin, digitalin, gitaloxin)	Blurred vision, GI upset, dizziness, muscle weakness, tremors, dysrhythmias
Garcinia	<i>Garcinia cambogia</i>	Brindberry, hydroxycitric acid	Weight loss	Hydroxycitric acid	May lower serum glucose concentration in diabetics
Garlic	<i>Allium sativum</i>	Allium, stinking rose, rustic treacle, nectar of the gods, da san	Infections, coronary artery disease, hypertension	Alliin, Ajoene	Contact dermatitis, gastroenteritis, antiplatelet effects

Gentian	<i>Gentiana lutea</i> , <i>Gentiana</i> spp	Bitter root, gall weed Longdancao	Bitter, digestive stimulant, emmenagogue	—	None reported
Germander	<i>Teucrium chamaedrys</i>	Wall germander	Antipyretic, abdominal disorders, wounds, diuretic, cholestatic	Furan neoderodane diterpenes	Hepatotoxicity, hepatitis, cirrhosis
Ginger	<i>Zingiber officinale</i>		Carminative, diuretic, antiemetic, stimulant, motion sickness	Volatile oil, phenol	Possible increased risk of bleeding when taken with anticoagulants
Ginkgo	<i>Ginkgo biloba</i>	Maidenhair tree, kew tree, tebonin, tanakan, rokan, kaveri	Asthma, chilblain, digestive aid, cerebral dysfunction	Ginkgo flavone glycosides and terpene lactones (ginkgolides and bilobalide)	Extracts: GI upset, headache, skin reaction; leaf: antiplatelet; allergic reactions
Ginseng	<i>Pinax ginseng</i> <i>Pinax quinquefolius</i> <i>Pinax pseudoginseng</i>	Ren shen	Respiratory illnesses, gastrointestinal disorders, impotence, fatigue, stress, adaptogenic, external demulcent	Ginsenosides: panaxin, ginsenin	Ginseng abuse syndrome
Glucamannan	<i>Amorphophallus konjac</i>	Konjac, konjac mannan	Weight-reducing agent; "grapefruit diet," increase viscosity, decrease gastric emptying	Polysaccharides	Esophageal and lower GI obstruction
Glucosamine	2-amino-2-deoxyglucose	Chitosamine	Wound-healing polymer, antiarthritic	Glucosamine	None reported
Goat's rue	<i>Goats officinalis</i>	French lilac, French honeysuckle	Antidiabetic	Galagone, paragalegine	Hypoglycemia
Guj	<i>Lycium barbarum, chinense</i>	Wolfberry, gou qi zi	Protect liver, improve eyesight, enhance immune system	Carotenoids, lutein, atropine	May inhibit warfarin metabolism
Goldenseal	<i>Hydrastis canadensis</i>	Orange root, yellow root, tumeric root	Astringent, GI disorders, dysmenorrhea	Berberine, hydrastine	GI upset, Very high doses: paralysis and respiratory failure
Gordolobo yerba	<i>Senecio longiloba</i> <i>Senecio aureus</i> , <i>Senecio vulgaris</i> <i>Senecio spartioides</i>	Groundsel, liverroot	Gargle, cough, emmenagogue	Pyrolizidine alkaloids	Hepatic venoocclusive disease
Gotu Kola	<i>Centella asiatica</i>	Hydnocotyle, Indian pen- nywort, talpetrako	Wound healing, tonic, antibacterial	Asiaticoside, asiatic acid, madecassic acid	Contact dermatitis
Grape seed	<i>Vitis vinifera</i>		Antioxidant: antiaging, peripheral vascular disease	Proanthocyanidins	None reported
Green tea	<i>Camellia sinensis</i>	Green tea	Antioxidant, weight loss, reduce cholesterol	Polyphenols (catechins and epigallocatechin gallate)	Hepatotoxicity from green tea extracts
Hawthorn	<i>Crataegus arjancantha</i> <i>Crataegus laevigata</i> <i>Crataegus monogyna</i>	English hawthorn, haw, maybush, whitethorn	Hypertension, CHF, dysrhythmias, antispasmodic, sedative	Hyperoside, vitesin, procyanidin	Hypotension, sedation
Heliotrope	<i>Crotalaria spectabilis</i> , <i>Heliotropium europaeum</i>	Rattlebox, groundsel, viper's bugloss, bush tea	Cancer	Pyrolizidine alkaloids	Hepatic venoocclusive disease
Herbane	<i>Hieronymus niger</i>	Fetid nightshade, poison tobacco, insane root, stinky nightshade	Sedative, analgesic, antispas- modic, asthma	Hyoscyamine, hyosine	Anticholinergic toxicity
Holly	<i>Ilex aquifolium</i> <i>Ilex opaca</i> <i>Ilex vomitoria</i>	English holly, American holly, and yaupon	Tea, emetic, CNS stimulant, coronary artery disease	Saponins	GI upset

Hoodia	<i>Hoodia gordonii</i>	Xhoba, khoba, Ghaap, hoodia cactus, South African desert cactus	Weight loss, appetite suppressant	PS7	None reported
Horny goat weed	<i>Epimedium grandiflorum</i>	Ying yang huo	Aphrodisiac	Icarin	None reported
Hydrangea	<i>Hydrangea arborescens</i> <i>Hydrangea paniculata</i>	Seven bark, wild hydrangea	Diuretic, stimulant, carminative, cystitis, renal calculi, asthma	Hydrangin, saponin	Dizziness, chest pain, GI upset
Iboga	<i>Lobelia inflata</i>	Ibogaine	Aphrodisiac, stimulant, hallucinogen, addiction treatment	Indole alkaloid: ibogaine	Hallucinations, cholinergic hyperactivity
Ingula	<i>Callipepla laureola</i>		Zulu traditional remedy	Potassium atractylatellike compound	Vomiting, hypoglycemia, centrilobular hepatic necrosis
Jalap	<i>Ipomoea purga</i>	—	Cathartic	Convulxin	Profuse watery diarrhea
Jimsonweed	<i>Datura stramonium</i>	Datura, stramonium, apple of Peru, Jamestown weed, thornapple, tolgucha	Asthma	Atropine, scopolamine, hyoscyamine, stramonium	Anticholinergic toxicity
Juniper	<i>Juniperus communis</i> <i>Juniperus macrocarpa</i>	Oil of sabinol	Toxic, diuretic, urinary antiseptic, emmenagogue, abortifacient	Monoterpenes (terpinen-4-ol)	Renal irritation
Kava kava	<i>Piper methysticum</i>	Awa, kava-kava, kava, tonga	Relaxation beverage, uterine relaxation, headaches, colds, wounds, aphrodisiac	Kava lactones Flavokawin A and B	Mild euphoria, muscle weakness Skin discoloration, hepatic failure
KH-3	Procaine HCl	Gerovital-H3, GH-3, Gerovita	Cerebral atherosclerosis, dementia, arthritis, hair loss, hypertension	Procaine	Procaine toxicity
Khat	<i>Catha edulis</i>	Qat, kat, chaat, Khat es Salabin, Tchaat, Gat	CNS stimulant, depression, fatigue, obesity, ulcers	Cathine, cathinone	Euphoria, dysphoria, stimulation, sedation, psychological dependence, leukoplakia
Kola nut	<i>Cola acuminata</i>	Botu cola, kola nut	Digestive aid, tonic, aphrodisiac, headache, diuretic	Caffeine, theobromine, kolanin	CNS stimulant
Kombucha	Mixture of bacteria and yeast	Kombucha tea, kombucha mushroom, Manchurian tea	Memory loss, premenstrual syndrome, cancer	—	Hepatotoxicity/metabolic acidosis
Levant berry	<i>Anemone cocculea</i>	Fish killer, fishberry, huckle elderberry, Indian berry, louseberry, poisonberry	Vermifuge, malaria	Picrotoxin	CNS stimulant, GI upset
Licorice	<i>Glycyrrhiza glabra</i>	Spanish licorice, Russian licorice, gancan	Gastric irritation	Glycyrrhizin	Flaccid weakness, dysrhythmias, hypokalemia, lethargy
Lipoic acid		D-Lipoic acid, thioctic acid	Antioxidant, diabetes, neuropathy, AIDS	Lipoic acid	Hypoglycemia
Lobelia	<i>Lobelia inflata</i>	Indian tobacco	Antispasmodic, respiratory stimulant, relaxant	Pyridine-derived alkaloids (lobeline)	Nicotine toxicity
Mace	<i>Myristica fragrans</i>	Mace, maceade, seed cover of nutmeg	Diarrhea, mouth sores, insomnia, rheumatism	Myristicin (methoxysafrole)	Hallucinations
Mandrake	<i>Mandragora officinarum</i>		Hallucinogen	Atropine, scopolamine, hyoscyamine	Anticholinergic toxicity
Mate	<i>Ilex paraguayensis</i>	Paraguay tea	Stimulant	Caffeine	Caffeine toxicity

Milk thistle	<i>Cnicus marianus</i> <i>Silybum marianum</i>	Mary thistle	Liver disease, antidepressant, HIV	Silymarin	None
Mistletoe	<i>Viscum album</i> <i>Phoradendron</i> <i>leucarpum</i>	Isador	Antispasmodic, calmative, cancer, HIV	Vicetoxins, lectins	GI upset, bradycardia, delirium
Morinda	<i>Morinda citrifolia</i>	Noni, Indian mulberry, noni/ nono, mengkudu, bajitan	Antioxidant, stress, depression	Polysaccharides, anthraqui- none: damncanthol	None
Morning glory	<i>Ipomoea purpurea</i> <i>L. violacea</i>	Heavenly blue, blue star, flying saucers	Hallucinogen	Lysergic acid lamide Ergine	LSD-like toxicity
Myrrh	<i>Commiphora molmol</i>	Mulmul, ogo, heesabol	Astringent, anesthetic, emmenagogue, antispasmodic, cancer	Sesquiterpenes	None
Nutmeg	<i>Myristica fragrans</i>	Mace, roo dou kou	Hallucinogen, abortifacient, aphrodisiac, GI disorders	Myristicin	Hallucinogen, GI upset
Oleander	<i>Nerium oleander</i>	Adelfa, laurier rose, rosa laurel, rose bay, rose francesca	Cardiac disorders, asthma, coma, cancer, epilepsy	Oleandrin, nerolin, Gentiobi- sycosandrin, odorside A	GI upset, diarrhea, dysrhythmias
Olive leaf extract	<i>Olea europaea</i>		Immunostimulant	Oleuropein	
Ostrich fern	<i>Matteuccia struthiopteris</i>	—	Laxative	—	GI upset if eaten undercooked
Parsley	<i>Petroselinum crispum</i>	Rock parsley, garden parsley	Diuretic, uterine stimulant, abortifacient	Myristicin, apiol, furocouma- rin, psoralen	Uterine stimulant, photosensitization
Passion flower	<i>Passiflora incarnata</i>	Passiflora, maypop	Insomnia, analgesic stimulant	Harmala alkaloids	Sedation
Pau d'Arco	<i>Tibebuia spp</i>	Ipe roxo, lapacho, taheebo tea	Tonic, "blood builder," cancer, AIDS	Naphthoquinone derivative: lapachol	GI upset anemia, bleeding
Pennyroyal oil	<i>Hedeoma pulegioides</i> <i>Mentha pulegium</i>	American pennyroyal, Squawmint, mosquito plant	Abortifacient, regulate men- struation, digestive tonic	Cyclohexanone: pulegone	Hepatotoxicity
Periwinkle	<i>Catharanthus roseus</i>	Red periwinkle, Madagascar or Cape periwinkle, old maid, church-flower, ram-goat rose, "myrtle," magdalena	Hallucinogen, ocular inflammation, diabetes, hemorrhage, insect stings, cancers	Vincristine, vinblastine Indole alkaloid	Vincristine/vinblastine toxicity
Podophyllum	<i>Podophyllum peltatum</i> <i>Podophyllum hexandrum</i> <i>Podophyllum emodi</i>	Mandrake, mayapple, American podophyllum Indian podophyllum guijiu	Cathartic, purgative	Podophyllin	Podophyllin toxicity
Pokeweed	<i>Phytolacca americana</i> <i>Phytolacca decandra</i>	American nightshade, Cancer jalap, inkberry, poke, scoke	Arthritis, emetic, purgative	Saponins: phytolactigenin, jalagonic acid, phytolac- cogenic acid, pokeweed nitrogen	Gastroenteritis, blurry vision, weakness, respiratory distress, seizures, leukocytosis
Pycnogenol (French maritime pine bark extract)	<i>Pinus pinaster</i>	Pine bark extract	Antioxidant, hypertension vascular disease, ADHD	Proanthocyanidins	None reported
Pygeum	<i>Prunus africana</i>	Pygeum africanum, African prune	Impotence, male infertility, prostate cancer, benign prostatic hypertrophy	β -sitosterol, pentacyclic terpenes, ferulic esters	None reported
Quinine	<i>Cinchona succirubra</i> <i>Cinchona calisya</i> <i>Cinchona ledgeriana</i>	Red bark, Peruvian bark, Jesuit bark, China bark Cinchona bark, quinaquina, fever tree	Malaria, fever, indigestion Cancer Hemorrhoids, varicose veins, abortifacient	Quinine	Cinchonism
Red bush tea	<i>Aspalathus linearis</i>	Rooibos tea	Anxiety, allergic dermatitis, indigestion	Aspalathin, isochlorogenic acid, orientin, rutin	None reported
Red clover	<i>Tribulus terrestris</i>	Trefoil, purple clover, wild clover	Boonchitis, cough, eczema, acne, premenstrual syndrome	Isoflavones: biochanin A and farnesochlorogenic	None reported

Rehmannia	<i>Rehmannia glutinosa</i>	Sheng di huang, Chinese foxglove root	Arthritis, asthma, kidney and liver tonic, aplastic anemia, hypopituitarism	Iodoids and iridoid glycosides	None reported
Reishi mushroom	<i>Ganoderma lucidum</i>	Ling zhi, lucky fungus	Hepatitis, promote longevity	Polysaccharide peptides, triterpenes (ganoderic acid)	None reported
Rosavin	<i>Rhodiola rosea</i>	Golden root, cimulin	Weight loss, aphrodisiac, adaptogen, improve cognitive function	Loastralin, rosavin, rosin, rosarin, salidroside	None reported
Rose hips	<i>Rosa canina</i>	Hip berry, rose haws, rose hips, wild boar fruit	Vitamin C supplement, Upper respiratory infection, diarrhea	Vitamin C, vitamin K	May interfere with warfarin
Rue	<i>Ruta graveolens</i>	Herb of grace, herb grass	Emmenagogue, antispasmodic, abortifacient	Furocoumarins, bergapten, xanthoxanthin	Photosensitization
Sage	<i>Salvia officinalis</i>	Garden sage, true sage, scarlet sage, meadow sage	Antiseptic, astringent, hormonal stimulant, carminative, abortifacient	Camphor, thujone	Seizures
St. John's wort	<i>Hypericum perforatum</i>	Klamath weed, John's wort, goatweed, sha-rongye	Anxiety, depression, gastritis, insomnia, promote healing, AIDS	Hyperforin, Hypericin	Occasional photosensitization, drug interaction: CYP3A4
Salvia	<i>Salvia divinorum</i> <i>Salvia miltiorrhiza</i>	Sierra mazateca, diviners sage, magic mint, Maria pastora	Hallucinogen, renal disease	Salvinorin A Lithospermate B	Hallucinations
SAM-e	S-adenosyl-L-methionine		Antidepressant, osteoarthritis, liver disease	S-adenosyl-L-methionine	None reported
Sassafras	<i>Sassafras albidum</i>	Lauraceae	Stimulant, antispasmodic, purifier	Sassafras oil (10% Saffrole)	Hepatotoxicity, carcinogen (?)
Saw palmetto	<i>Serenoa repens</i>	Sabal, American dwarf palm tree, cabbage palm	Genitourinary disorders, increase sperm production, sexual vigor	5- α reductase inhibitor	Diarrhea
Schisandra	<i>Schisandra chinensis</i>	Wu zhi zi, five flavored seed	Tonic, aphrodisiac, liver treatment, sedative	Schisandrins, nigric acid	None reported
Scullcap	<i>Scutellaria lateriflora</i>	Skullcap, helmetflower, hood wort	Tranquillizer, tonic, antispasmodic	Flavone glucuronides and flavanone glucuronides	None reported
Senna	<i>Cassia acutifolia</i> <i>Cassia angustifolia</i>	Alexandrian senna	Stimulant, laxative, diet tea	Anthraquinone, glycosides (sennosides)	Diarrhea, CNS effects
Shark cartilage	<i>Squalus acanthias</i> <i>Sphyrna lewini</i>	—	Cancer: inhibit tumor angiogenesis	Chondroitin sulfate	None reported
Siberian ginseng	<i>Eleutherococcus senticosus</i>	Devil's shrub, eleuthera, eleutherococ	Adaptogens, hypertension, immunomodulator	Ginsenosides	None reported
Slippery elm	<i>Ulmus rubra</i> <i>Ulmus fulva</i>	Elm, elm bark, red elm	Acne, boils, indigestion, abortifacient	Polysaccharide mucilage Oleomin	Contact dermatitis
Soapwort	<i>Saponaria officinalis</i>	Blowwort, bouncing bet, dog doves, fuller's herb, latherwort	Acne, psoriasis, eczema, boils, natural soaps	Saponins	Intravenous: highly toxic Oral: None
SOD	Superoxide dismutase	Ogokein, ormetein, palosein	Improve health, lengthen lifespan, chronic bladder disease, paraquat poisoning	Superoxide dismutase	None reported
Soy isoflavone	<i>Glycine max</i>		Menopausal symptoms, heart disease	Phytoestrogens: genistein, daidzein, glycitein	Cancer
Squill	<i>Urginea maritima</i> <i>Urginea indica</i>	Sea onion Red Squill	Diuretic, emetic, cardiotonic, expectorant	Cardioactive steroid, scillaren A	Emesis, dysrhythmias

Stephania	<i>Stephania tetrandra</i>	Han fang ji	Fever, pain, inflammation, decrease water retention	—	None (misidentification of this herb with aristolochia (Guang fang ji) resulted in cases of Chinese herb nephropathy)
Stevia	<i>Stevia rebaudiana</i>	Sweet leaf of Paraguay	Sugar-free sweetener, diabetes, hypertension, weight-loss aid	Stevioside	None reported
Tu-san-chi	<i>Gymura segetum</i>	—	Tea	Pyrolizidine alkaloids	Hepatic veno-occlusive disease
Tonka bean	<i>Dipteryx odorata</i> , <i>Dipteryx oppositifolia</i>	Tonquin bean, coumaru	Food, cosmetics	Coumarin	Anticoagulant effect
Tung seed	<i>Aleurites moluccana</i> <i>A. fordii</i>	Tung, candlenut, candleberry, barnish tree, balucanat, otahrite	Wood preservative (oil), purgative (oil), asthma treatment (seed)	Saponins, phytotoxins	GI upset, hyporeflexia, death; latex dermatitis
Valerian	<i>Valeriana officinalis</i>	Radix valerianae, Indian Valerian, red valerian	Anxiety, insomnia, antispasmodic	— Valepotriates, valerenic acid	Sedation
Vitex	<i>Vitex agnus-castus</i>	Chasteberry, chaste tree, agnus castus	Premenstrual syndrome, female infertility	—	None reported
White cohosh	<i>Actaea alba</i> , <i>Actaea rubra</i>	Baneberry, snakeberry, doll's eyes, coralberry	Emmenagogue	Protoanemonin	Headache, GI upset, delirium, circulatory failure
White willow bark	<i>Salix alba</i>	Common willow, European willow	Fever, pain astringent	Salicin	Salicylate toxicity
Wild lettuce	<i>Lactuca virosa</i> (<i>Lactuca sativa</i>)	Lettuce opium, prickly lettuce	Sedative, cough suppressant, analgesic	—	None reported
Woodruff	<i>Galium odoratum</i>	Sweet woodruff	Wound healing, tonic, varicose veins, antispasmodic	Coumarin	None reported
Wormwood	<i>Artemisia absinthium</i>	Absinthies	Sedative, analgesic, antihelminthic	Thujone	Psychosis, hallucinations, seizures
Yarrow	<i>Achillea millefolium</i>	Bloodwort, carpenter's grass, dog daisy, nosebleed	Heal wounds, viral symptoms, digestive disorder, diuretic	—	Contact dermatitis
Yew	<i>Taxus baccata</i>	Yew	Antispasmodic, cancer remedy	Taxine (sodium channel blocker)	Dizziness, dry mouth, bradycardia, cardiac arrest
Yohimbe	<i>Pausinystalia yohimbe</i>	Yohimbé, yohimbebe	Body building, aphrodisiac, stimulant	Alkaloid yohimbine from bark	Hypertension, abdominal pain, weakness

(AC = central nervous system, GI = gastrointestinal)

Direct Health Risks

Direct health risks include pharmacologically predictable and dose-dependent toxic reactions, idiosyncratic toxic reactions, long-term toxic effects, and delayed toxic effects. For example, ingestion of aconite tea, in the suggested dose, causes tachydysrhythmias and hypotension. Idiosyncratic toxic reactions cannot be predicted on the basis of principal pharmacologic properties. For example, ingestion of chamomile tea results in anaphylaxis in a small subset of patients with probable allergies to the Compositae family. Long-term toxic effects occur only after chronic usage. For example, chronic use of herbal anthranoid laxatives results in muscular weakness from hypokalemia. Delayed toxic effects include carcinogenicity and teratogenicity. Another example is urothelial cancers in humans as a result of prolonged consumption of Aristolochia.¹¹⁹

Indirect Health Risks

Herbal use may adversely impact health by altering previous conventional prescription medication therapy. A patient may

discontinue or become less compliant with previous therapy, with untoward consequences. Alternatively, the addition of an herbal preparation may affect the pharmacologic effect, principally by altering the bioavailability or clearance of concurrently used medications. Coadministration of St. John wort, an inducer of CYP3A4, with the protease inhibitor indinavir, which is metabolized by this enzyme, may result in decreased plasma indinavir concentrations and potentially decreased antiretroviral activity.¹²⁸

Most Widely Used Herbal Supplements

The most popular herbal supplements (food, drug, and mass-market retail outlets {excluding warehouse buying clubs and convenience store sales}) in the United States in 2011 are listed below in order of sales.¹⁴ The top five represent more than \$100 million of sales.¹⁴

1. **Cranberry** (*Vaccinium macrocarpon*)—Cranberry is a popular remedy for treatment of urinary tract infections, but it appears to be ineffective in preventing recurrent urinary tract infections.⁴¹ Cranberry appears to be safe in appropriate doses.⁷
2. **Soy** (*Glycine max*)—Soy contains two popularly advertised ingredients: protein and isoflavones. Diets high in soy protein are associated with decreased cholesterol and low-density lipoprotein concentrations. Soy isoflavone supplements (genisten, daidzen) are phytoestrogens (plant estrogens) that currently are suggested as alternative remedies for treatment of menopausal symptoms. There is current concern regarding the effect of high concentrations of isoflavones on the risk of developing breast cancer in postmenopausal women and breast cancer survivors.
3. **Saw palmetto** (*Serenoa repens*)—Saw palmetto is a popular remedy for benign prostatic hypertrophy. Saw palmetto inhibits 5- α -reductase. However, a recent study observed that saw palmetto did not improve symptoms or objective measures of benign prostatic hypertrophy.¹¹ Saw palmetto appears to be safe in appropriate doses.^{110,122}
4. **Garlic** (*Allium sativum*)—Garlic has been used as a food and a medicine since ancient times. As a herb, it is used for treatment of infections, hypertension, colic, and cancer.⁶⁴ The intact cells of garlic contain the odorless, sulfur-containing amino acid derivative (+)-S-allyl-L-cysteine sulfoxide, also known as alliin. When crushed, alliin is converted to allicin (diallyl thiosulfinate), which has antibacterial and antioxidant activity and gives the herb its characteristic odor and flavor. Adverse effects of garlic extracts include contact dermatitis, gastroenteritis, nausea, and vomiting. Several constituents of garlic, such as ajoene, possess antiplatelet effects. Consequently, garlic may increase the risk of bleeding in individuals who are also taking antithrombotics.⁶⁴
5. **Ginkgo** (*Ginkgo biloba*)—This herb contains ginkgo flavone glycosides, known as ginkgolides, that are reputed to have antioxidant properties, inhibit platelet aggregation, and increase circulation. It is popularly used to treat or prevent both Alzheimer disease and peripheral vascular disease. However, two studies in 2002 and 2008 failed to demonstrate any improvement in cognitive function in healthy elderly subjects without cognitive impairment.^{52,143} In appropriate doses ginkgo appears to be safe, although it may increase the risk of bleeding in individuals who are also taking antithrombotics or anticoagulants.^{61,110,122}
6. **Milk thistle** (*Silybum marianum*)—Milk thistle contains silymarin and silibinin, and is a popular remedy for treatment of liver dysfunction. It is also an investigational antidote for *Amanita* mushroom poisoning. It appears to be safe (Antidotes in Depth: A36).
7. **Echinacea** (*Echinacea purpurea*, *angustifolia*)—Echinacea is a reputed immunostimulant and is a popular herbal remedy for cold symptoms. However, an NCCAM-funded study was unable to detect any improvement in preventing these symptoms.¹⁵² Echinacea appears to be safe in appropriate doses.⁷¹ Rare individuals develop allergic reactions when taking echinacea.¹¹⁵
8. **Black cohosh** (*Cimicifuga racemosa*)—Black cohosh is used for the treatment of premenstrual syndrome and as alternative estrogen replacement therapy for relief of perimenopausal symptoms. It also is used as a treatment for arthritis and as a mild sedative. Black cohosh appears to be safe in appropriate doses.^{13,78}
9. **St. John wort** (*Hypericum perforatum*)—St. John wort is used to treat depression and is also used as a topical remedy for cuts, bruises, and wounds.¹³⁵ It has lost its popularity as an AIDS treatment because of the lack of clinical efficacy.⁷² The active ingredients are hyperforin and hypericin. Its antidepressant properties likely derive from the ability of hyperforin to inhibit the reuptake of serotonin, dopamine, norepinephrine, γ -aminobutyric acid, and glutamate.²² A major study in 2002 demonstrated that St. John wort is ineffective in treating depression.⁸¹ Acute toxicity appears limited to photosensitization reactions. St. John wort induces CYP3A4 and may interact with medications metabolized by this enzyme (eg, indinavir, oral contraceptives, cycloserine).^{103,128} Hyperforin is a weak monoamine oxidase inhibitor, raising concerns about interactions with the selective serotonin reuptake inhibitors.¹²⁸
10. **Ginseng** (*Panax ginseng*)—Ginseng is the common name for deciduous, perennial plants of the genus *Panax*. *Panax ginseng* is native to Korea, China, Japan, and Russia. *Panax quinquefolius* is the common ginseng species in North America and grows abundantly throughout the central and eastern regions of Canada and the United States. Ginseng

preparations have been used in China for treatment of respiratory illnesses, GI disorders, impotence, fatigue, and stress (“adaptogenic effect”). It is regarded as a tonic and panacea (hence the name *Panax*, meaning “all healing”). Its only recognized use in the United States is as an external demulcent.^{66,96,111} Ginseng provides a good example of the complexity of the biochemistry and pharmacologic effects of herbs. The active components of ginseng are called ginsenosides and include panaxin, panax acid, panaquin, panacen, sapogenin, and ginsenin. Its general metabolic effects include decreasing serum glucose and serum cholesterol concentrations; increasing erythropoiesis, hemoglobin production, and iron absorption from the GI tract; increasing blood pressure and heart rate; GI motility; and CNS stimulation. Ginseng abuse syndrome, which consists of hypertension, nervousness, sleeplessness, and morning diarrhea, has been described following long-term use of ginseng.^{66,139,140} Ginseng use may reduce the anticoagulant effect of warfarin.^{82,169}

11. Valerian (*Valeriana officinalis*)—Valerian is a popular remedy for treatment of anxiety and is also used as a sleeping aid. Valerian appears to be safe in appropriate doses. Valerian may potentiate sedation in patients taking sedative-hypnotics.¹²²

12. Green tea—Green tea is a popular antioxidant used to prevent chronic disease as well as for weight reduction. It is also touted to protect against cancer and decrease cholesterol concentrations. A 2006 study in Japan observed that green tea consumption was associated with a decreased mortality from all causes of cardiovascular disease.⁹¹ Polyphenols contained in green tea including catechins and epigallocatechin gallate are responsible for its antioxidant properties. Although green tea consumption is considered to be safe, recent case reports describing the development of acute hepatitis following ingestion of green tea extracts or infusions suggest that idiosyncratic hepatotoxicity may occur in rare individuals.^{12,15,62,68,83,84}

13. Evening primrose (*Oenothera biennis*)—Evening primrose contain *cis*- γ -linoleic acid, a prostaglandin E₁ precursor. This herb is a popular remedy for treatment of premenstrual syndrome, diabetes, eczema, and rheumatoid arthritis. Evening primrose appears to be safe in appropriate doses. This herb may lower the seizure threshold in epilepsy.

TOXICITY OF SIGNIFICANT HERBAL PREPARATIONS

Cardiovascular Toxins

Aconite. Aconites (caowu, chuanwu, and fuzi) are the dried root stocks of the *Aconitum* plant.¹⁴⁶ In China, aconite usually is derived from *Aconitum carmichaelii* (chuan wu) or *A. kuznezoffii* (caowu). In Europe and the United States, aconite is derived from *A. napellus*, commonly known as monkshood or wolfsbane. The tubers are the most toxic part of the plant. When ingested, both cardiac and neurologic toxicity occur. Aconite poisoning is far more common in Asia, especially China.³⁹ In Hong Kong, it is responsible for the majority of serious poisonings from Chinese herbal preparations.^{35,37,39}

Aconite toxicity is caused by C19 diterpenoid-ester alkaloids, including aconitine, mesaconitine, and hypaconitine.²¹ Aconitine increases sodium influx through the sodium channel, increasing inotropy while delaying the final repolarization phase of the action potential and promoting premature excitation.⁷⁶ Sinus bradycardia and ventricular dysrhythmias can occur.³⁸ Symptoms can occur from 5 minutes to 4 hours after ingestion. Paresthesias of the oral mucosa and entire body may be followed by nausea, vomiting, diarrhea, and hypersalivation, and then by progressive skeletal muscle weakness. Fatalities may occur with doses as low as 5 mL aconite tincture, 2 mg pure aconite, or 1 g dried plant. Atropine may be of value in treating bradycardia or hypersalivation.¹⁴⁷ Although no antidote is available, anecdotal reports suggest the use of amiodarone, flecainide, lidocaine, and procainamide for ventricular tachydysrhythmias.^{147,168} Pharmacologic principles support the use of these sodium channel blockers. One case of aconite-induced refractory tachydysrhythmias was successfully managed with a ventricular assist device.⁵⁶ In a case series of two aconite-poisoned patients, reversal of aconite-induced ventricular dysrhythmias was attributed to the use of charcoal hemoperfusion for aconitine removal.^{98,99}

Ch'an Su. Ch'an Su is a traditional herbal remedy derived from the secretions of the parotid and sebaceous glands of the toad *Bufo bufo gargarizans* or *Bufo melanostictus*. This remedy is traditionally used as a treatment for congestive heart failure.⁸⁹ Ch'an Su contains two groups of toxic compounds: digoxinlike cardioactive steroids consisting of bufadienolides and the alkaloid bufotenin. Clinical findings following ingestion are similar to cardioactive steroid poisoning, including gastrointestinal symptoms and dysrhythmias. It was also marketed as an aphrodisiac for its purported topical anesthetic effects and sold under names such as “Stone,” “Love Stone,” “Black Stone,” and “Rock Hard.” Between 1993 and 1996 in New York City, several fatalities were associated with the ingestion of Ch'an Su marketed as a topical aphrodisiac.²⁵ Severe toxic reactions and death are reported after mouthing toads, “toad licking,” or eating an entire toad, or ingesting toad soup, or toad eggs.¹⁸ Assays for serum digoxin unpredictably cross-react with bufadienolides, but may qualitatively assist in making a presumptive diagnosis (Table 45–1). Digoxin-specific Fab was successfully used to treat Ch'an Su poisoning and should be empirically administered for any suspected case of cardiotoxicity from Ch'an Su or other cardioactive

steroid^{18,141} (Chap. 65).

Central Nervous System Toxins

Absinthe. Wormwood (*Artemisia absinthium*) extract is the main ingredient in absinthe, a toxic liquor that was outlawed in the United States in 1912. This volatile oil is a mixture of α - and β -thujone (Table 45–3).¹⁶⁷ Chronic absinthe use caused “absinthism,” characterized by psychosis, hallucinations, intellectual deterioration, and seizures. The most famous victim of absinthism may have been Vincent Van Gogh, who is thought to have suffered from this disorder in the later part of his life.⁵ A thujone-free wormwood extract now is used for flavoring vermouth and pastis. A case of wormwood-induced seizures, rhabdomyolysis, and acute kidney failure was described involving a patient who purchased from the Internet and consumed approximately 10 mL essential oil of wormwood, assuming it was absinthe liquor.¹⁶⁴ Treatment remains supportive.

TABLE 45–3. Constituent Psychoactive Xenobiotics in Herbal Preparations

Labeled Ingredient	Scientific Name	Usage	Active Ingredients	Effects
Broom	<i>Cytisus scoparius</i>	Smoke for relaxation	L-Sparteine	Sedative-hypnotic
California poppy	<i>Eschscholzia californica</i>	Smoke as marijuana substitute	Alkaloids and glucosides	Euphoriant
Catnip	<i>Nepeta cataria</i>	Smoke or tea as marijuana substitute	Nepetalactone	Euphoriant
Ch'an Su	<i>Bufo bufo gargarizans</i> <i>Bufo bufo melanostictus</i>	Smoke or lick for hallucinations	Bufofenin	Hallucinogen
Cinnamon	<i>Cinnamomum camphora</i>	Smoke with marijuana	?	Stimulant
Dove	<i>Syzygium aromaticum</i>	Smoke in cigarette/"kreteks"	Eugenol	Euphoriant
Damiana	<i>Turnera diffusa</i>	Smoke as marijuana substitute	?	Stimulant/hallucinogen
Goldenseal	<i>Hydrastis canadensis</i>	Ingest to mark detection of opioid, marijuana, or cocaine in urinary drug screen	—	No evidence
Hops	<i>Humulus lupulus</i>	Smoke or tea as sedative and marijuana substitute	Humulone, lupulone → methylbutenol	Sedative (mild)
Hydrangea	<i>Hydrangea paniculata</i>	Smoke as marijuana substitute	Hydrangin, saponin	Stimulant
Ibogaine	<i>Tabernaemontana iboga</i>	Stimulant, hallucinogen	Ibogaine	Hallucinogen
Juniper	<i>Juniperus macrocarpa</i>	Smoke as hallucinogen	?	Hallucinogen
Kava kava	<i>Piper methysticum</i>	Smoke or tea as marijuana substitute	Kava lactones	Hallucinogen
Kola nut	<i>Cola acuminata</i>	Smoke, tea, or capsules as stimulant	Caffeine, theobromine, kolanin	Stimulant
Lobelia	<i>Lobelia inflata</i>	Smoke or tea as marijuana substitute	Lobeline	Euphoriant
Mandrake	<i>Mandragora officinarum</i>	Tea as hallucinogen	Atropine, scopolamine	Hallucinogen
Mate	<i>Ilex paraguayensis</i>	Tea as stimulant	Caffeine	Stimulant
Mormon tea	<i>Ephedra nevadensis</i>	Tea as stimulant	Ephedrine	Stimulant
Morning glory	<i>Ipomoea violacea</i>	Seeds have hallucinogens	D-lysergic acid amide (ergine)	Hallucinogen
Nutmeg	<i>Myristica fragrans</i>	Tea as hallucinogen	Myristicin	Hallucinogen
Passion flower	<i>Passiflora incarnata</i>	Smoke, tea, or capsules as marijuana substitute	Harmala alkaloids	Stimulant (mild)
Periwinkle	<i>Catharanthus roseus</i>	Smoke or tea as euphoriant	Indole alkaloids	Hallucinogen
Prickly poppy	<i>Argemone mexicana</i>	Smoke as euphoriant	Protopine, berberine, isoquinolones	Analgesic
Sahia	<i>Sahia divinatorum</i>	Smoked, chewed	Sahivorium A	Hallucinogen
Snakeroot	<i>Rauwolfia serpentina</i>	Smoke or tea as tobacco substitute	Reserpine	Tranquilizer
Thorn apple	<i>Datura stramonium</i>	Smoke or tea as tobacco substitute or hallucinogen	Atropine, scopolamine	Hallucinogen
Tobacco	<i>Nicotiana spp</i>	Smoke as tobacco	Nicotine	Stimulant
Valerian	<i>Valeriana officinalis</i>	Tea or capsules	Choline, valericine alkaloids	Tranquilizer
Wild lettuce	<i>Lactuca sativa</i>	Smoke as opium substitute	Unknown	Analgesic (mild)
Wormwood	<i>Artemisia absinthium</i>	Smoke or tea as relaxant	Thujone	Analgesic
Yohimbe	<i>Pausanistalia yohimbe</i>	Smoke or tea as stimulant	Yohimbine	Hallucinogen (mild)

Anticholinergics: Henbane, Jimson Weed, Mandrake. Many plants contain the belladonna alkaloids atropine (D,L-hyoscyamine), hyoscyamine, and scopolamine (L-hyoscyne). They may still be used therapeutically for treatment of asthma and occasionally are mistakenly included in herbal teas.³⁴ Signs and symptoms of anticholinergic poisoning include

mydriasis, diminished bowel sounds, urinary retention, dry mouth, flushed skin, tachycardia, and agitation. Mildly poisoned patients usually require only supportive care and sedation with intravenous benzodiazepines. Intravenous physostigmine reverses anticholinergic poisoning; however, its use should be limited to treatment of moderately to severely symptomatic patients because inappropriate use may cause seizures and dysrhythmias (Antidotes in Depth: A9).

Ephedra. Members of the genus *Ephedra* generally consist of erect evergreen plants resembling small shrubs.¹⁵⁰ Common names include sea grape, ma-huang, yellow horse, desert tea, squaw tea, and Mormon tea. *Ephedra* species have a long history of use as stimulants and for management of bronchospasm. They contain the alkaloids ephedrine and, in some species, pseudoephedrine.^{132,150} In large doses, ephedrine causes nervousness, headache, insomnia, dizziness, palpitations, skin flushing, tingling, vomiting, anxiety, restlessness, mania, and psychosis. The treatment is similar to that for other CNS stimulants (Chap. 76). In a published review of 140 reports of adverse events associated with ephedra use submitted to the FDA, 62% of cases (82) were considered “probable” or “possibly” related to ephedra use. Hypertension was the most commonly reported adverse effect (17 cases), followed by palpitations or tachycardia (13 cases), strokes (10 cases), and seizures (seven cases). Ten reported cases resulted in death. Thirteen cases resulted in permanent disability.⁷⁴ In 2002, the FDA banned the sale of ephedra-containing dietary supplements.¹⁵⁵ However, other herbal preparations, such as bitter orange (*Citrus aurantia*), contain ephedra-like alkaloids (synephrine) and are still widely available.^{115,121} Exposures may result in cardiovascular toxicity.^{116,121}

Nicotinics: Betel Nut, Blue Cohosh, Broom, Chestnut, Lobelia, Tobacco. Betel (*Areca catechu*) is chewed by an estimated 200 million people worldwide for its euphoric effect. As an herb, it is used as a digestive aid and as a treatment for cough and sore throat. Its active ingredient is arecoline, a direct-acting nicotinic agonist. The betel leaf also contains a phenolic volatile oil and an alkaloid capable of producing sympathomimetic reactions. Arecoline is a bronchoconstrictor, although weaker than methacholine, and may exacerbate bronchospasm in asthmatic patients chewing betel nut.¹⁴⁹ Treatment for betel nut toxicity is supportive. Long-term use of betel nut is associated with leukoplakia and squamous cell carcinoma of the oral mucosa.¹²⁰

Many other herbal preparations have nicotinic effects. Examples of plants and their nicotinic ingredient include blue cohosh¹³, methylcytisine, broom, l-sparteine, chestnut, esculin, lobelia, lobeline, and tobacco/nicotine (Chap. 85).

Other herbs that have CNS activity include valerian (sedation), kava kava (sedation), Japanese star anise (seizures), nutmeg (hallucinations),¹⁶⁵ mace (hallucinations), and iboga (hallucinations).

Gastrointestinal Toxins

Goldenseal. Goldenseal (*Hydrastis canadensis*) originally was used by the Cherokees and other Native Americans as a dye and an internal remedy.⁶⁹ Today, it is used as an astringent, as a remedy for mucous membranes or GI tract disorders, and as treatment for menorrhagia. Goldenseal is reputed to mask the presence of illicit drugs on urinary drug screens, although multiple studies indicate goldenseal does not affect the results of urinary drug screens.^{44,118,124} This myth originated in the murder-mystery *Stringtown on the Pike* (1900), which was written by the internationally known plant pharmacist Uri Lloyd. In this novel, one of the major characters is accused of murder by poisoning with strychnine but is posthumously exonerated with evidence that hydrastine (the active alkaloid in goldenseal) and morphine cross-react to produce a positive color assay for strychnine.⁶⁰ Appropriate usage of this herb is thought to be safe, but ingestion of large amounts can cause vomiting, diarrhea, convulsions, paralysis, and respiratory failure. In cases of large ingestions, the patient should receive supportive and symptomatic care.

Hepatotoxins

Pennyroyal. Pennyroyal oil is a volatile oil extract from the leaves of *Mentha pulegium* and *Hedeoma pulegioides* plants. Herbalists use pennyroyal oil as an abortifacient and to regulate menstruation. It is also used as a flea/mosquito repellent and as a fragrance. The abortive effect is thought to be caused by irritation and contraction of the uterus.¹⁴⁶ Pennyroyal usually is ingested as a strong tea prepared from the leaves or as the oil itself. It is cited as causative in several well-documented cases of hepatic failure following ingestion of as little as 15 mL of the oil.^{3,8} The postulated mechanism is direct hepatotoxicity following glutathione depletion from the cyclohexanone pulegone and its cytochrome P450 (CYP1A2, CYP2E1, CYP2C19)-dependent toxic metabolites that include menthofuran.⁸⁷ On autopsy, vacuolization of the white matter of the midbrain was reported in both a fatal human exposure and in animal models.^{7,123} Because pulegone depletes hepatic glutathione stores, N-acetylcysteine treatment may be beneficial^{3,19} (Antidotes in Depth: A3). In an animal model, pretreatment with cytochrome P450 inhibitors cimetidine (CYP1A2, CYP2C19) and disulfiram (CYP2E1) reduced pulegone-induced hepatotoxicity.¹⁴⁵ It may be reasonable to consider use of cytochrome P450 inhibitors in the treatment of pennyroyal-poisoned patients; however, evidence of clinical benefit in humans currently is lacking.

Pyrrolizidine Alkaloids. Pyrrolizidine alkaloids are hepatotoxins found in many plants, including heliotrope (*Heliotropium*), ragwort or groundsel (*Senecio*), rattlebox (*Crotalaria*), and comfrey (*Symphytum*).^{127,131} Examples of other

plants and products containing pyrrolizidine alkaloids include borage (*Borago officinalis*), coltsfoot (*Tussilago farfara*), and T'u-san-chi'i (*Gynura segetum*).^{79,90,132} The alkaloids undergo metabolism to pyrroles, which serve as biologic alkylating agents.⁷⁹ The pyrroles cause hepatic sinusoidal hypertrophy and venous occlusion, resulting in hepatic veno-occlusive disease, hepatomegaly, cirrhosis, and possibly hepatic carcinoma. Chronic low dose exposure may cause pulmonary toxicity resulting in pulmonary artery hypertension and right ventricular hypertrophy. Consumption of “bush” tea, prepared from the leaves of the *Crotalaria* plant, is considered an endemic problem in Jamaica. Epidemics have also occurred in Afghanistan and India, where ingestion of contaminated cereals containing *Heliotropium* and *Crotalaria* seeds resulted in reports of 1632 and 60 cases of venoocclusive disease, respectively.^{112,148} In Western countries, ingestion of herbal products containing *Senecio* and comfrey have led to several cases of hepatic venoocclusive disease.¹²⁷ Treatment of hepatic venoocclusive disease is supportive but may require liver transplantation in severe cases.

Several other herbal preparations are associated with hepatotoxicity.⁹³ These preparations include chaparral (*Larrea tridentata*),^{24,70} germander (*Teucrium chamaedrys*),⁹⁴ impilia (*Callilepis laureola*),⁹⁰ atractylis (*Atractylis gummifera*), sassafras (*Sassafras albidum*),¹³⁹ and kava kava (*Piper methysticum*).¹⁵⁷

Metals

Poisonings by metallic salts, including arsenic, cadmium, lead, and mercury, may occur following consumption of various types of herbal preparations^{27,30,46,132} (Chaps. 89, 91, 96, and 98). Treatment consists of ceasing consumption of the herbal product and use of an appropriate chelator when indicated.

Hai-ge-ten (clamshell powder) contamination with copper, chromium, arsenic, or lead is described in several case reports.^{75,104} Pay-loo-ah, a red and orange powder used by the Hmong people as a fever and rash remedy, was contaminated with lead.²⁶ Ayurvedic remedies are either herbal only or *rasa shastra*, which, based upon ancient traditional healing of India, deliberately combines metals such as gold, silver, copper, zinc, iron, lead, tin, and mercury and are used by the majority of the Indian population.^{28,129,130,137} Ghasard, Bola Goli, Kandu, and Moha Yogran Guggulu, traditional Indian remedies for abdominal pain, are associated with lead poisoning.^{27,138} One fatality from lead poisoning from Ghasard, Bola Goli, and Kandu is reported from the United States.²⁷ In one study, 20% of surveyed Ayurvedic products produced in South Asia and sold on a nonprescription basis in stores in the Boston area contained potentially harmful concentrations of lead, mercury, or arsenic.¹³⁶ A follow-up study determined that a similar 21% of Ayurvedic products sold through the Internet also contained potentially harmful concentrations of lead, mercury, or arsenic irrespective of whether manufacture occurred in the United States or India.¹³⁷

These same investigators recently studied the lead, mercury, and arsenic concentrations in the United States and Indian manufactured Ayurvedic medicines sold via the Internet demonstrating that 20% of these were contaminated with one of these metals, all exceeding one or more standards for acceptable daily intake of a toxic metal.¹³⁷ Azarcon (lead tetroxide) and greta (lead oxide) are used by an estimated 7.2% to 12.1% of Mexican-Hispanic families for treatment of *empacho*. In Spanish, *empacho* means “blocked intestine,” but it refers to any type of chronic digestive problem, including such diverse symptoms as constipation, diarrhea, nausea, vomiting, anorexia, apathy, and lethargy.^{31,33} Azarcon and greta are fine powders with total lead contents varying from 70% to more than 90%.^{16,32}

Herbal balls, hand-rolled mixtures of herbs and honey produced in China, are often associated with arsenic and mercury contamination.⁵⁵ Examples include An Gong Niu Huang Wan, Da Huo Luo Wan, and Niu Huang Chiang Ya Wan.

Renal Toxins

Aristolochia. An epidemic of renal failure in Belgium was linked to the substitution of *Aristolochia fangchi*, also known as birthwort, heart-wort, and fangchi, for another Chinese herbal, *Stephania tetrandia*, in the formulation of a weight-loss regimen.^{161,162} Of 70 identified cases of renal fibrosis, 30 patients developed chronic renal failure. Aristolochic acid in *Aristolochia* causes renal fibrosis, which typically becomes clinically apparent 12 to 24 months after the initial injury. Patients with *Aristolochia*-induced nephropathy also have an increased risk for developing urothelial cancer.¹¹⁹

Miscellaneous

Chamomile Tea. Chamomile tea is a popular herbal drink made from chamomile flower heads. Anaphylactic reactions can occur in patients allergic to ragweed, asters, chrysanthemums, or other members of the *Compositae* family.^{10,23} Such reactions are rare but can be life threatening. The patient need not have severe allergies or be highly atopic to experience a cross-reaction.

Chinese Patent Medicines

Chinese patent medicines, a component of traditional Chinese medicine (TCM), contain traditional herbals, formulated into

tablets, capsules, syrups, powders, ointments, and plasters, for easy use. They are produced by poorly regulated Chinese pharmaceutical agencies and are highly susceptible to adulteration (intentional) or contamination (inadvertent). They are often sold by nonherbalists at convenience stores in packages with incomplete documentation of ingredients and often are not labeled in English. Many contain undocumented pharmaceuticals, like to increase their effectiveness, and improve sales among non-TCM users in Western nations. For example, in 2007, 90 Chinese patent medicines randomly purchased in New York City's Chinatown identified five samples containing nine undisclosed Western medications, including chlormethiazole, chlorpheniramine, diclofenac, chlordiazepoxide, hydrochlorothiazide, triamterene, diphenhydramine, and sildenafil citrate.¹⁰⁹

Treatment

A specific treatment strategy should emphasize identification of the specific herbal preparation(s) used by the patient, concurrent medication(s), and medical illness(es). Because herbal preparation toxicity varies greatly depending on the preparation used, careful examination may be aided by knowledge of the herbal preparation. In most cases, supportive care and discontinuation of the herbal preparation(s) are sufficient. Some herbal toxicities require specific laboratory analysis and therapy (Table 45–1).

All adverse events associated with herbal preparations should be reported to the local poison control center or to FDA MedWatch by phone at 1-800-FDA-1088 or online at <https://www.fda.gov/medwatch>.

SUMMARY

- Although most herbal preparation users will experience no ill effects, both herb users and clinicians should be aware that these preparations are pharmacologically active, have the potential for toxicity, and are not as closely regulated by the FDA (or any governmental agency) as pharmaceuticals.
- Herbal preparation users should be aware that these preparations are poorly studied with scientific proof of efficacy lacking for most preparations. No standards exist for their manufacture, quality, or control and many herbal products do not contain the purported amount of the active ingredient. Some herbal products do not even contain the specified active ingredient.
- Many herbal stores are staffed by untrained personnel who may dispense incorrect medical advice and unfounded claims concerning their products.^{126,160}
- Clinicians should be familiar with herbal preparations and their potential for drug interactions and adverse events.

46 IRON

Jeanmarie Perrone

Iron

Molecular weight	=	55.85 Da
Serum normal concentration	=	80–180 µg/dL
	=	14–32 µmol/L

HISTORY AND EPIDEMIOLOGY

Iron poisoning has become uncommon. This success may underscore the importance of prevention by interventions gleaned from poison center data and poison prevention advocacy. Blister packaging, smaller dosages, and education of parents and health care professionals have led to a great decline in iron poisoning in the past two decades. Unfortunately, however, significant iron poisonings still occur, and clinician must be aware of the nuances of presentation and diagnosis to optimize iron poisoning management. Clinicians must be vigilant for signs of serious iron poisoning and be ready to intervene if gastrointestinal (GI) toxic effects are followed by acid–base disturbances, altered mental status, or hemodynamic compromise.

Iron salts such as ferrous sulfate have been used therapeutically for thousands of years and continue to be available, both with and without prescription, for the prevention and treatment of iron deficiency anemia in patients of all ages. Despite this long history of use, the first reports of iron toxicity only occurred in the mid-twentieth century. Since then, numerous cases of iron poisoning and fatalities have been reported, mostly in children.^{57,59} In 1950, the manufacturer of “fersolate,” an iron supplement, included a package warning: “Excessive doses of iron can be dangerous. Do not leave these tablets within reach of young children, who may eat them as sweets with harmful results.”⁸⁷

The incidence of iron exposures continued to increase in the 1980s, ultimately becoming, in the 1990s, the leading cause of poisoning deaths reported to poison centers among children younger than 6 years (Chap. 136). This problem was publicized in a case series of tragic fatalities involving five toddlers in Los Angeles during a 6-month period in 1992, all of whom were exposed to prenatal vitamins containing iron.⁹⁴ The association between death and prenatal vitamins highlights the availability of these potentially lethal medications in the homes of families with young children, ironically as a result of more attentive prescribing of prenatal iron. A case control study in Canada identified a fourfold increase in the risk of iron poisoning to the older sibling of a newborn during the first postpartum month.⁴² The authors concluded that almost one-half of all hospital admissions of young children for iron poisoning could be prevented by safer storage of iron supplements in the year before and the year after the birth of a sibling.

In 1997, the US Food and Drug Administration (FDA) mandated that all iron salt-containing preparations display warning labels regarding the dangers of pediatric iron poisoning.²³ In addition to the warning labels, the FDA launched an educational campaign to alert caregivers and prescribers of the potential toxicity of iron supplements.²⁴ Other preventive initiatives instituted by the FDA in 1997 included unit dosing (blister packs) of prescriptions for preparations containing more than 30 mg of elemental iron and limitations on the number of pills dispensed (ie, maximum 30 day supply).²⁴ These efforts to prevent unintentional exposure dramatically decreased the incidence of poisoning and were pivotal in decreasing morbidity and mortality associated with iron poisoning⁸¹ (Chap. 135). However, in 2003, the FDA rescinded the blister packaging requirement in response to a lawsuit charging that the FDA did not have jurisdiction over the packaging of dietary supplements.²² Although isolated fatalities continue to occur,⁵⁸ the trend in the National Poison Data System suggests they are becoming less common (Chap. 136). Iron poisoning may also occur after ingestion of other iron salts used in industry, such as ferric chloride.¹⁰² Ingestion of metallic iron does not result in toxicity.

PHARMACOLOGY, PHARMACOKINETICS, AND TOXICOKINETICS

Iron is an element critical to organ function. As a transition metal, iron can easily accept and donate electrons, thereby shifting the ferric (Fe^{3+}) and ferrous (Fe^{2+}) oxidation states (Chap. 12). This redox capacity elucidates the role of iron in multiple protein and enzyme complexes, including cytochromes and myoglobin, although it is principally incorporated into hemoglobin in erythrocytes. Whereas insufficient iron availability results in anemia, excess total body iron results in hemochromatosis.

The body cannot directly excrete iron, so iron stores are regulated by controlling iron absorption from the GI tract. The absorption of iron salts (iron ions as Fe^{2+} or Fe^{3+}) occurs predominantly in the duodenum, and is determined by the iron requirements of the body. In iron deficiency, iron absorption and uptake into intestinal mucosal cells may increase from a normal 10% to 35% to as much as 80% to 95%. After uptake into the intestinal mucosal cells, iron is either stored as ferritin and lost when the cell is sloughed or released to transferrin, a serum iron binding protein. In therapeutic doses, some of these processes become saturated, and absorption into the intestinal cell may be limited. However, in overdose, the oxidative effects of iron on GI mucosal cells lead to dysfunction of this regulatory balance, and passive absorption of iron increases down its concentration gradient⁸⁰ (see Pathophysiology).

Iron supplements are available as the iron salts ferrous gluconate, ferrous sulfate, and ferrous fumarate and as the nonionic preparations carbonyl iron and polysaccharide iron. Additional sources of significant quantities of iron are vitamin preparations, especially prenatal vitamins (Table 46–1). Toxic effects of iron poisoning occur at doses of 10 to 20 mg/kg elemental iron which is defined as the amount of iron ion present in an iron salt (Table 46–1). Significant GI toxic effects occurred in human adult volunteers who ingested 10 to 20 mg of elemental iron/kg.^{9,50} In one volunteer study, six participants who ingested 20 mg/kg elemental iron developed nausea and voluminous diarrhea within 2 hours, and five of the six subjects had serum iron concentrations above 300 $\mu\text{g/dL}$.⁹

TABLE 46–1. Common Iron Formulations and Their Elemental Iron Contents

<i>Iron Formulation</i>	<i>Elemental Iron (%)</i>
Ionic	
Ferrous chloride	28
Ferrous fumarate	33
Ferrous gluconate	12
Ferrous lactate	19
Ferrous sulfate	20
Nonionic	
Carbonyl iron	98 ^a
Polysaccharide iron	46 ^a

^aAlthough these nonionic iron formulations contain higher elemental iron content than ionic formulations, carbonyl iron and iron polysaccharide have better therapeutic-to-toxic ratios due to their limited gastrointestinal absorption rates.

In another study of human volunteers who ingested 5 to 10 mg/kg elemental iron in the form of chewable iron containing vitamins, peak serum iron concentrations occurred between 4.2 and 4.5 hours in all participants.⁵⁰ In overdose, peak concentrations of iron are thought to occur 2 to 6 hours after ingestion, depending on the iron preparation.^{9,50} Chewable vitamins continue to entice children with their sweet taste and recognizable character shapes, increasing the risk of significant exposure. Children’s chewable multivitamins contain less iron per tablet (10–18 mg of elemental iron) than typical prenatal vitamins (65 mg of elemental iron). Iron toxicity still results when large quantities of chewable children’s vitamins are ingested, but the therapeutic-to-toxic ratio is improved.² One animal study paradoxically demonstrates higher iron concentrations after ingestion of equivalent elemental iron doses of chewable versus solid iron tablets.⁶¹ This finding was attributed, in part, to the limited gastric irritation associated with the chewable iron preparations, resulting in less vomiting.

Iron supplements are also available in two nonionic forms, carbonyl iron and iron polysaccharide, both of which appear to be less toxic after overdose than are iron salts,⁷⁶ despite their high elemental iron content.⁴⁶ Carbonyl iron is a form of elemental iron that is highly bioavailable in therapeutic doses compared to other forms of iron because of its high elemental iron content and its very fine, spherical particle size (5 μm).³³ In a rat model of iron toxicity, carbonyl iron had a median lethal dose (LD_{50}) of 50 g/kg compared with an LD_{50} of 1.1 g/kg for ferrous sulfate.⁹⁷ No significant toxicity in humans exposed to carbonyl iron has been reported.⁷⁶ Iron polysaccharide contains approximately 46% elemental iron by weight. It is synthesized by neutralization of a ferric chloride carbohydrate solution. This form of iron also appears to have much lower toxicity than iron salts. The estimated LD_{50} in rats is more than 5 g/kg body weight. Retrospective poison

center data have shown little toxicity from either of these products.⁴⁶

Parenteral iron, such as iron dextran, intravenously administered to patients with kidney failure and chronic anemia, may also result in toxicity, as well as anaphylactoid reactions. Newer parenteral formulations, including iron sucrose and sodium ferrous gluconate, appear to be safer.²¹

PATHOPHYSIOLOGY

Iron is active in many oxidation reduction (redox) reactions. Iron catalyzes the generation of hydroxyl radicals intracellularly through the Fenton reaction and Haber-Weiss cycle and mediates its toxicologic effects as an inducer of oxidative stress and inhibitor of several key metabolic enzymes (Chap. 12). Reactive oxygen species oxidize membrane-bound lipids and cause loss of cellular integrity and tissue injury.^{70,72}

The initial oxidative damage to the GI epithelium produced by iron-induced reactive oxygen species permits iron ions to enter the systemic circulation. Iron ions are rapidly bound to circulating binding proteins, particularly transferrin. After transferrin is saturated with iron, “free” iron (ie, iron not bound to a transport protein) is widely distributed to the various organ systems, where it promotes damaging oxidative processes. A postmortem series of 11 patients who died from iron ingestion substantiated these findings with measurements of elevated iron concentrations in most major organs examined, including the stomach, liver, brain, heart, lung, small bowel, and kidney.⁶⁵ Congestion, edema, necrosis, and iron deposition in the gastric and intestinal mucosa, as well as hemorrhage and congestion in the lungs, are noted on postmortem examination.^{30,31,52}

Iron ions disrupt critical cellular processes such as mitochondrial oxidative phosphorylation. Subsequent buildup of unused hydrogen ions normally incorporated into the synthesis of adenosine triphosphate leads to liberation of H^+ and development of metabolic acidosis (Chap. 13). In addition, absorption of iron from the GI tract leads to conversion of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}). Ferric iron ions exceed the binding capacity of plasma, leading to formation of ferric hydroxide and release of three protons ($Fe^{3+} + 3H_2O \rightarrow Fe(OH)_3 + 3H^+$).^{70,80}

Decreased cardiac output contributes to shock in animals.^{91,100} Although this finding is often attributed to decreased preload and relative bradycardia,⁹¹ a direct negative inotropic effect of iron on the myocardium is also demonstrated in animal models.³ Reports of early coagulopathy unrelated to hepatotoxicity⁸³ led to the identification of free iron as an inhibitor of thrombin formation and the reduction of the effect of thrombin on fibrinogen.⁷³

CLINICAL MANIFESTATIONS

Classic teaching posits five clinical stages of iron toxicity based on the pathophysiology of iron poisoning.^{6,41,68} Although these stages are conceptually important, they are of limited benefit to clinicians managing poisoned patients. Although the stages are typically described in approximate postingestion time frames, a clinical stage should never be assigned based solely on the number of hours postingestion because patients do not necessarily follow the same temporal course through these stages.

The first stage of iron toxicity is characterized by nausea, vomiting, abdominal pain, and diarrhea. These “local” toxic effects of iron predominate, and subsequent salt and water depletion contribute to the ill appearance of the iron poisoned patient. Intestinal ulceration, edema, transmural inflammation, and, in some extreme cases, small-bowel infarction and necrosis may occur.^{25,71,85} Hematemesis, melena, or hematochezia may cause hemodynamic instability. GI symptoms always occur after significant overdose. Conversely, the absence of signs and symptoms, specifically vomiting, in the first 6 hours following ingestion, essentially excludes serious iron toxicity.

The second, or “latent,” stage of iron poisoning commonly refers to the period 6 to 24 hours after ingestion when resolution of GI symptoms occurs, but systemic toxicity has not yet developed. Delineation of this stage may have evolved from early case reports of patients whose GI symptoms had resolved before subsequent deterioration.⁸⁷ This second stage is not a true quiescent phase because ongoing cellular organ toxicity occurs during this phase.⁶ Although clinicians should be wary of patients who no longer have active GI complaints after iron overdose, most such patients have, in fact, recovered and are not in the latent phase. Patients in the latent phase generally have lethargy, tachycardia, or metabolic acidosis. They should be readily identifiable as clinically ill despite resolution of their GI symptoms. In summary, patients who have remained well since ingestion and who have stable vital signs, a normal mental status, and a normal acid–base balance will have a benign clinical course.

Patients who progress to the third, or “shock,” stage of iron poisoning have profound toxicity. This stage may occur in the first few hours after a massive ingestion or 12 to 24 hours after a more moderate ingestion. The etiology of shock may be multifactorial, resulting from hypovolemia, vasodilation, and poor cardiac output,^{91,100} with decreased tissue perfusion and an ongoing metabolic acidosis. Iron-induced coagulopathy may worsen bleeding and hypovolemia.⁸³ Systemic toxicity

produces central nervous system effects with lethargy, hyperventilation, seizures, or coma. The fourth stage of iron poisoning is characterized by hepatic failure, which may occur 2 to 3 days after ingestion.³⁰ The hepatotoxicity is directly attributed to iron uptake by the reticuloendothelial system in the liver, where it causes oxidative damage.^{26,101} The fifth stage of iron toxicity rarely manifests. Gastric outlet obstruction, secondary to strictures and scarring from the initial GI injury, may develop 2 to 8 weeks after ingestion.^{29,36,85}

Patients treated for chronic iron overload are at increased risk for *Yersinia enterocolitica* infection. Iron is a required growth factor for *Y. enterocolitica*; however, the bacterium lacks the siderophore to solubilize and transport iron intracellularly. Because deferoxamine is a siderophore, it fosters the growth of *Y. enterocolitica*. Thus, patients with chronic iron overload or acute poisoning develop *Yersinia* infection or sepsis as a complication of iron poisoning or deferoxamine therapy.^{11,54,57,78} *Yersinia* infection should be suspected in patients who experience abdominal pain, fever, and bloody diarrhea after resolution of iron toxicity. In this setting, cultures should be obtained, fluid and electrolyte repletion accomplished, and fluoroquinolones or third-generation cephalosporin therapy initiated.

DIAGNOSTIC TESTING

Radiography

Iron is available in many forms, and the different preparations vary with respect to radiopacity on abdominal radiography.⁷⁷ Factors such as the time since ingestion and elemental iron content of the tablets are also important.^{60,77} Liquid iron formulations and chewable iron tablets typically are not radiopaque.¹⁹ A retrospective review of iron ingestions in children revealed that abdominal radiographs were positive in only one of 30 patients who ingested chewable iron containing vitamin tablets.¹⁹ Because adult tablet preparations have a higher elemental iron content and do not readily disperse, they tend to be more consistently radiopaque.⁶⁰ Finding radiopaque pills on an abdominal radiograph is helpful in guiding and evaluating the success of GI decontamination.³⁷ However, the absence of radiographic evidence of tablets is not a reliable indicator to exclude potential toxicity.^{60,64} Most patients can be managed without abdominal radiographs, given their lack of sensitivity.

Laboratory Studies

Various laboratory studies are used as surrogate markers to assess the severity of iron poisoning. An anion gap metabolic acidosis and an elevated lactate concentration may develop in patients with serious iron ingestions. Serial electrolyte measurements may be used to assess progression and response to volume replacement. Anemia may result from GI blood loss, but may not be evident initially because of hemoconcentration secondary to plasma volume loss.

Although one small retrospective study of iron-poisoned children found that a white blood cell count (WBC) above 15,000/mm³ or a blood glucose concentration above 150 mg/dL was 100% predictive of iron concentration above 300 µg/dL (a marker for clinical risk),⁴⁹ three subsequent similar studies were unable to validate this association.^{12,48,64} In practice, an elevated WBC or glucose concentration in the setting of a known or suspected iron ingestion should raise concern about an elevated serum iron concentration; however, assessment of the signs and symptoms of the patient is more reliable. Most importantly, normal WBC and glucose concentrations do not reliably exclude toxicity.

Although iron poisoning remains a clinical diagnosis, serum iron concentrations can be used effectively to gauge toxicity and the success of treatment.⁶ In the previously mentioned human volunteer study of six adults who ingested 20 mg/kg of elemental iron, all six adults demonstrated significant GI toxicity, and the four who required intravenous (IV) fluid resuscitation had peak serum iron concentrations in the range of 300 µg/dL between 2 and 4 hours after ingestion.⁹ Serum iron concentrations between 300 and 500 µg/dL usually correlate with significant GI toxicity and modest systemic toxicity. Concentrations between 500 and 1000 µg/dL are associated with pronounced systemic toxicity and shock.⁹⁵ Concentrations above 1000 µg/dL are associated with significant morbidity and mortality.⁹⁵ Although elevated serum iron concentrations may be an additional indicator of potentially serious toxicity, lower concentrations cannot be used to exclude the possibility of serious toxicity. A single serum iron concentration may not represent a peak concentration or may be falsely lowered by the presence of deferoxamine unless an atomic absorption technique is used for measurement.^{28,35}

Total iron-binding capacity (TIBC) is a measurement of the total amount of iron that can be bound by transferrin in a given volume of serum.²⁰ Previously, clinical iron toxicity was thought not to occur if the serum iron concentration was less than the TIBC, because insufficient circulating “free” iron was present to cause tissue damage. Although this is true, the error in interpretation results from the limitations of measuring TIBC values. Most importantly, the in vitro value of TIBC factitiously increases as a result of iron poisoning and thus has a tendency to apparently increase above a concurrently measured serum iron concentration.^{9,86} Because of many confounding issues, the TIBC as currently determined has no value in the assessment of iron-poisoned patients.

MANAGEMENT

Initial Approach

As with any serious ingestion, initial stabilization must include supplemental oxygen, airway assessment, and establishment of IV access. Evidence of hematemesis or lethargy after an iron exposure may be a manifestation of significant toxicity. Intravenous volume repletion should begin while orogastric lavage and whole bowel irrigation (WBI) are considered. In any lethargic patient who likely will deteriorate further, early endotracheal intubation may facilitate safe GI decontamination measures. Abdominal radiography may be used to estimate the iron burden in the GI tract given the caveats discussed earlier. Laboratory values, including chemistries, hemoglobin, iron concentration, coagulation, and hepatic profiles, are necessary in the sickest patients. An arterial or venous blood gas or a lactate concentration rapidly identifies a metabolic acidosis. Patients who appear well and had only one or two brief episodes of vomiting can be observed pending discharge. A serum iron concentration and most other laboratory testing are not needed in patients who have minimal symptoms and normal vital signs.

Limiting Absorption

GI decontamination procedures should be initiated after stabilization. Adequate gastric emptying is critical after ingestion of xenobiotics, such as iron, that are not well adsorbed to activated charcoal. Because vomiting is a prominent early symptom in patients with significant toxicity, induced emesis is not recommended. Orogastric lavage is more effective but may be of only limited value because of the large size and poor solubility of most iron tablets, their ability to form adherent masses,^{25,90} and their movement into the bowel several hours after ingestion.⁴³ The presence and location of radiopaque tablets on abdominal radiography can help guide orogastric lavage. Orogastric lavage will likely not be successful after iron tablets move past the pylorus, so WBI may be more effective (Fig. 46-1).

FIGURE 46-1A. A 17 month-old boy presented to the hospital with lethargy and hematemesis after a large ingestion of iron supplement tablets. Despite orogastric lavage and whole-bowel irrigation, iron tablets and fragments can be visualized in the stomach 4 hours after ingestion.

FIGURE 46–1B. The same 17 month-old child 10 hours after ingestion. Persistent iron pills were removed from the stomach by gastrotomy. No further radiopaque fragments can be visualized; however, ARDS is now visible.

Many strategies were used in the past in attempts to improve the efficacy of orogastric lavage. At the present time, no data support the use of oral deferoxamine,^{32,40,98,99,104} bicarbonate,^{15,16} phosphosoda,^{4,27} or magnesium.^{13,75,93} Although some of these techniques demonstrate efficacy, avoidance of the associated risks mandates using only 0.9% sodium chloride solution or tap water for orogastric lavage.

The value of WBI in patients with iron poisoning is supported primarily by case reports and one uncontrolled case series.^{18,43,82,83} However, the rationale for WBI use is logical, especially considering the limitations of other gastric decontamination modalities. The usual dose of WBI with polyethylene glycol electrolyte lavage solution (PEG-ELS) is 500 mL/h in children and 2 L/h in adults. This rate is best achieved by starting slowly and increasing as tolerated, often using a nasogastric tube and an infusion pump to administer large volumes. Antiemetics may be used to treat nausea and vomiting. A large volume (44 L) of WBI was administered safely over a 5-day period to a child who had persistent iron tablets on serial abdominal radiographs⁴³ (Antidotes in Depth: A2 and Chap. 8).

For patients with life-threatening toxicity who demonstrate persistent iron in the GI tract despite orogastric lavage and WBI, upper endoscopy or gastrotomy and surgical removal of iron tablets adherent to the gastric mucosa may be necessary and lifesaving.^{25,66,90}

Deferoxamine

Deferoxamine has been available since the 1960s as a specific chelator for patients with acute iron overdose or chronic iron overload (eg, multiple transfusions). Deferoxamine, which is derived from culture of *Streptomyces pilosus*, has high affinity and specificity for iron. In the presence of ferric iron (Fe^{3+}), deferoxamine forms the complex ferrioxamine, which is excreted by the kidneys,⁴⁴ usually imparting a reddish-brown color to the urine (Fig. 46–2). Deferoxamine chelates free iron and the iron transported between transferrin and ferritin^{51,67} but not the iron present in transferrin, hemoglobin, hemosiderin, or ferritin.^{5,44} Deferoxamine may work by other mechanisms in addition to binding excess systemic iron. Because 100 mg of deferoxamine chelates approximately 8.5 mg of ferric iron, recommended or typical therapeutic dosing of deferoxamine does not produce significant excretion of chelated iron in the urine, yet it does often result in dramatic clinical benefits (Antidotes in Depth: A7). Sufficient evidence suggests that deferoxamine can reach intracytoplasmic and

mitochondrial free iron, thereby limiting intracellular iron toxicity.⁵¹

FIGURE 46–2. These timed sequential urines were obtained from a small child with a serum iron concentration of 990 $\mu\text{g/dL}$ who was treated with intravenous deferoxamine. The characteristic color change is illustrated. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

IV administration of deferoxamine should be considered in iron-poisoned patients with any of the following findings: metabolic acidosis, repetitive vomiting, toxic appearance, lethargy, hypotension, or signs of shock. Deferoxamine administration is indicated for any patient with an iron concentration above 500 $\mu\text{g/dL}$. In patients manifesting serious signs and symptoms of iron poisoning, deferoxamine should be initiated as an IV infusion, starting slowly and gradually increasing to a dose of 15 mg/kg/h. Hypotension is the rate-limiting factor as more rapid infusions are used.^{38,96,98} Patients who appear toxic or have serum iron concentrations above 500 $\mu\text{g/dL}$ should be treated with IV deferoxamine. Patients who have concentrations below 500 $\mu\text{g/dL}$ and who do not appear toxic should be treated supportively without administration of parenteral deferoxamine (Fig. 46–3).

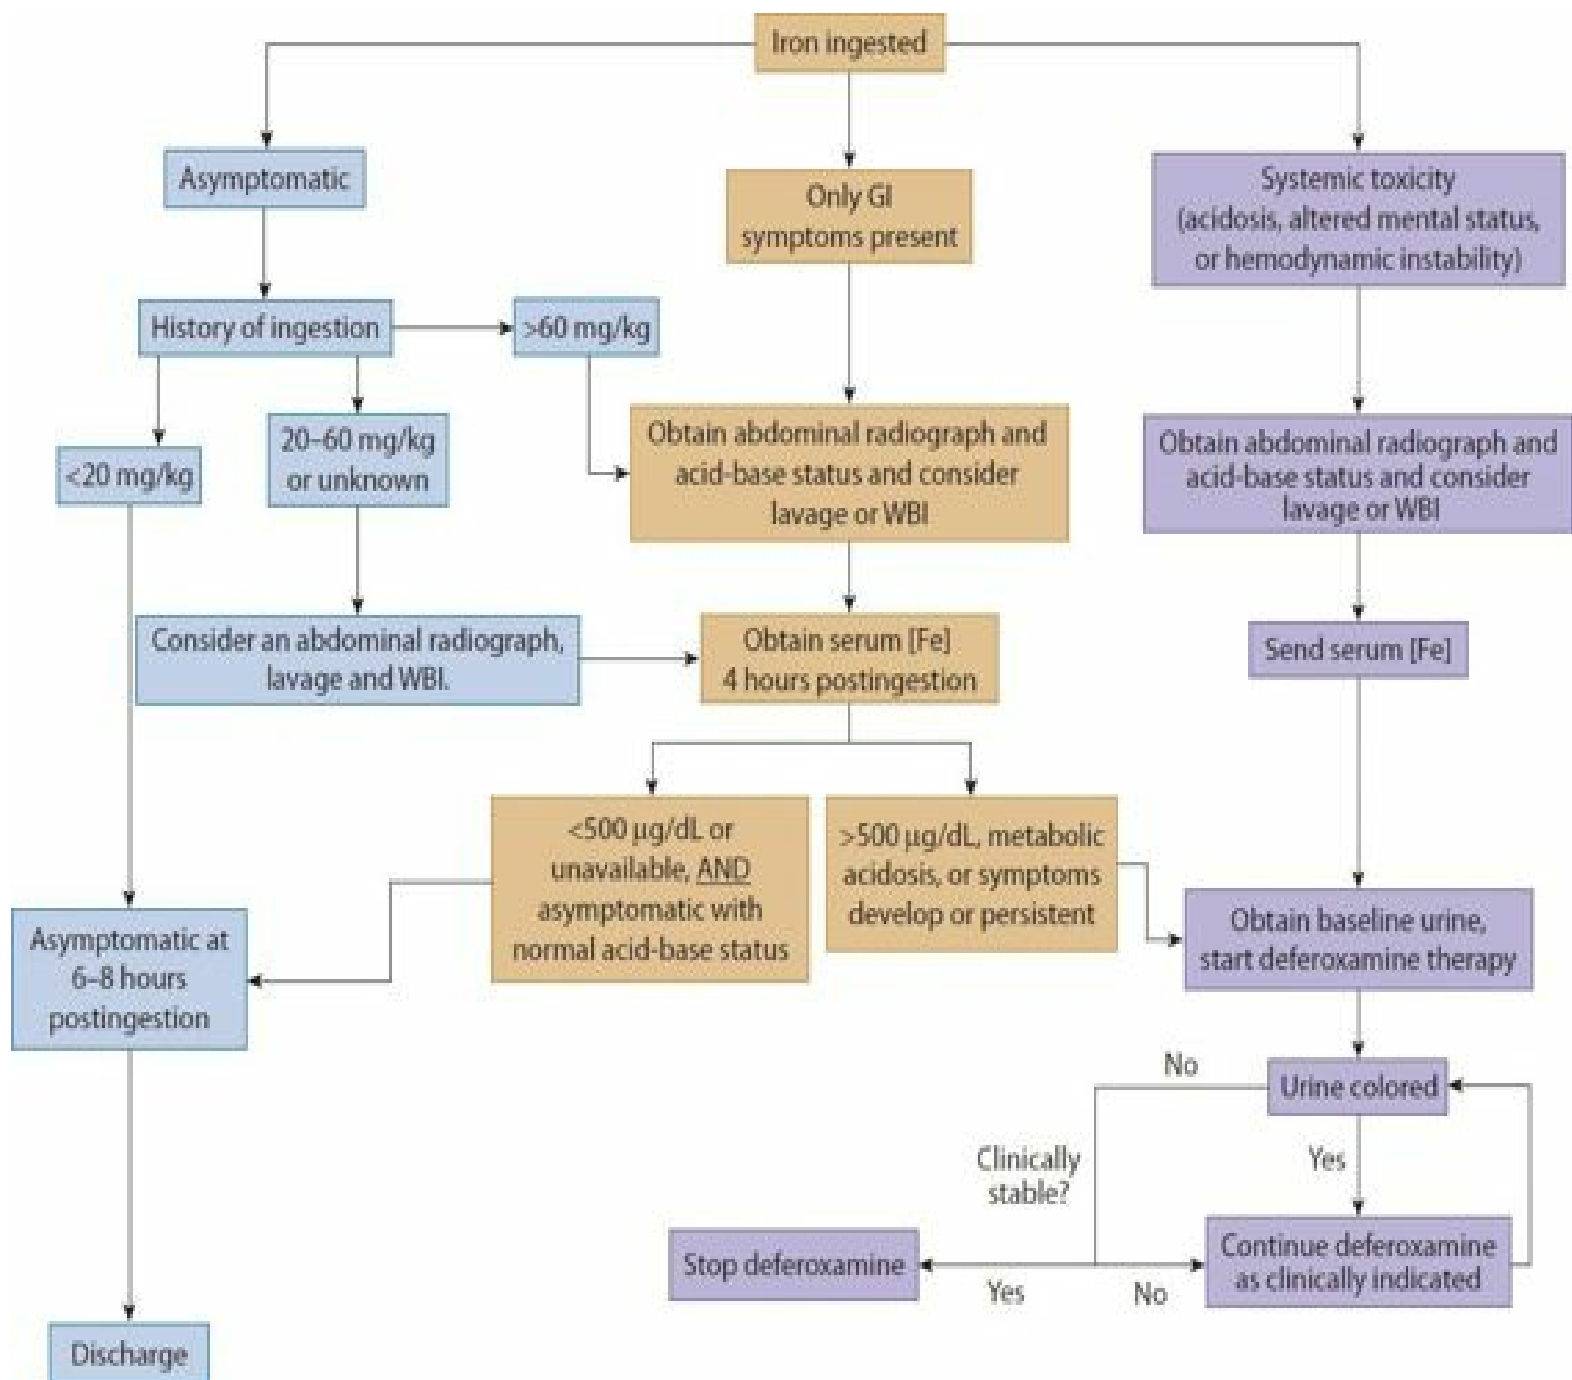

FIGURE 46–3. Algorithm for decision analysis following iron salt ingestion.

Clinicians have attempted to define the earliest clear end points for deferoxamine therapy because of possible deferoxamine toxicity. In one report, a urine iron-to-creatinine ratio (U_I/Cr) was used to determine if free iron excretion into the urine continued during deferoxamine therapy.¹⁰³ This ratio is a more objective measure of the presence of ferrioxamine in the urine than the less reliable and more subjective use of urinary color change.^{17,47,92} This method must be further studied clinically before its use can be advocated. Most authors agree that deferoxamine therapy should be discontinued when the patient appears clinically well, the anion-gap acidosis has resolved, and urine color undergoes no further change.⁵⁵ In patients with persistent signs and symptoms of serious toxicity after 24 hours of IV deferoxamine, continuing therapy should be undertaken cautiously, if at all, and perhaps at a lower dose due to the risk of adverse events (Antidotes in Depth: A7).

Adverse Effects of Deferoxamine. Most adverse effects of deferoxamine are reported in the setting of chronic administration for the treatment of hemochromatosis.^{39,63,74} The same effects, such as acute respiratory distress syndrome (ARDS), are also described after treatment for acute iron overdose.⁸⁴ Four patients with serum iron concentrations ranging from 430 to 620 $\mu\text{g/dL}$ developed ARDS after IV administration of deferoxamine for 32 to 72 hours.⁸⁴ An animal study revealed significantly increased pulmonary toxicity when high-dose deferoxamine therapy was administered in the presence of high concentrations of oxygen (75%–80% FiO_2).¹ The authors suggested that this effect was mediated via an oxygen free radical mechanism (Antidotes in Depth: A7).

Experimental Therapies

Deferasirox is an oral iron chelator approved by the FDA for the treatment of chronic iron overload that was studied as a potential iron antidote in human volunteers following supratherapeutic iron ingestion. In a randomized, double blind, placebo-controlled study, volunteers were administered 5 mg/kg iron followed by deferasirox or placebo.³⁴ Deferasirox resulted in lower iron concentrations in the treated group. However, concerns included the possibility that deferasirox may increase the absorption of iron complex and that the deferasirox dosing may need to be too high in patients with large exposures to effect these results. Further study is warranted before this therapy can be considered.

Patient Disposition

Many patients who ingest iron do not develop significant toxic effects. Recommendations for hospital referral of toddlers who ingest iron range from those with potential exposures of 20 mg/kg up to 60 mg/kg.^{6,47} These wide ranges probably result from the interpretation of retrospective studies in possibly “exposed” toddlers for whom the actual doses were estimated. Many authors suggest that doses were overestimated in patients who subsequently did not develop toxicity (Chap. 136). If a toddler remains asymptomatic or develops minimal or no GI manifestations after a 6 hour observation period in the emergency department, then discharge to an appropriate home situation can be considered. Patients who develop GI symptoms and signs of mild poisoning including vomiting and diarrhea can be observed as inpatients outside the intensive care unit. Patients who manifest signs and symptoms of significant iron poisoning, such as metabolic acidosis, hemodynamic instability, or lethargy, should be monitored and treated in an intensive care unit. Except in the case of carbonyl iron, hospital evaluation is recommended for any child with an estimated unintentional ingestion of more than 20 mg/kg of elemental iron. Children who appear well with unintentional ingestions between 10 and 20 mg/kg elemental iron and fewer than two episodes of vomiting should be closely followed at home in consultation with the poison control center.

Pregnant Patients

The frequent diagnosis of iron deficiency anemia during pregnancy has led to serious and even fatal iron ingestions in pregnant women.^{8,45,62,69,88} In all cases of toxic exposures during pregnancy, maternal resuscitation should always be the primary objective, even if an antidote poses a real or theoretical risk to the fetus. Unproven concerns regarding possible deferoxamine toxicity to the fetus have inappropriately, and at times, disastrously delayed therapy.^{62,79} These fears about fetal deferoxamine toxicity are not supported in either human or animal studies,^{14,53,89} which have demonstrated that neither iron nor deferoxamine is transferred to the fetus in appreciable quantities. An animal study demonstrated that fetal serum iron concentrations were not elevated and fetal deferoxamine concentrations could not be detected in pregnant near-term ewes poisoned with iron and treated with deferoxamine. Fetal demise under these circumstances presumably results from maternal iron toxicity and not from direct iron toxicity to the fetus. Thus, deferoxamine should be used to treat serious maternal iron poisoning and should never be withheld because of unfounded concern for fetal exposure to deferoxamine.

Adjunctive Therapies

Another modality used experimentally for treatment of iron intoxication is continuous arteriovenous hemofiltration (Chap. 10). In a study of five iron poisoned dogs, increased elimination of ferrioxamine in the ultrafiltrate was demonstrated when increasing doses of deferoxamine were infused into the arterial side of the system.⁷ A variant of this approach was utilized successfully in an iron poisoned toddler, who was treated with deferoxamine and venovenous hemofiltration.⁵⁶ Although the authors demonstrated a decreasing serum iron concentration, only a minimal concentration of iron was measured in the ultrafiltrate. This was presumed secondary to the large volumes of infusate used. Theoretically, ferrioxamine in the blood could be dialyzable with new high molecular-weight (large-pore) dialysis filters, but this technique has not been studied.

In toddlers with severe poisoning, exchange transfusion may help to physically remove free iron from the blood while replacing it with normal blood. Exchange transfusion in children is effective for poisonings such as aspirin or theophylline when the volume of xenobiotic distribution is small and removal from the blood compartment can be expected. Treatment with exchange transfusion has been suggested in iron poisoning based on early reports and more recently reported in the successful treatment of an 18 month-old child with iron poisoning.¹⁰ However, removal of blood volume must be performed cautiously because it may not be well tolerated by iron poisoned patients with hemodynamic instability.

SUMMARY

- Iron is available in multiple formulations: prenatal vitamins, ferrous gluconate, ferrous fumarate, and ferrous sulfate are most toxic.
- Iron toxicity is determined by the amount of elemental iron present: signs and symptoms occur following ingestions of 20 mg/kg of elemental iron.
- GI decontamination, including orogastric lavage and WBI using PEG-ELS, should be initiated when indicated as activated charcoal is ineffective in binding iron.

- Abdominal radiography may be helpful in determining the iron burden in the GI tract. However, not all preparations are radiopaque.
- GI signs and symptoms of nausea, vomiting, diarrhea, hematemesis, and abdominal pain are prominent in iron poisoning.
- Systemic iron toxicity leads to metabolic acidosis, hypotension, coagulopathy, and multiorgan system failure.
- Diagnosis and treatment of shock and metabolic acidosis, as well as chelation with deferoxamine, are critical.

A7 ANTIDOTES IN DEPTH

Deferoxamine

Mary Ann Howland

INTRODUCTION

Deferoxamine (DFO) is the parenteral chelator of choice for treatment of acute iron poisoning. Considering that DFO has been used to treat patients with acute iron overdose for more than 40 years,³³ there is still much that is unknown. No controlled studies have evaluated the efficacy or dosing of DFO. Animal studies and case series from the 1960s and 1970s form the basis for current use of DFO. This information has been supplemented since then by case reports and clinical experience. DFO is also used for chelation of aluminum in patients with chronic kidney failure. The merits of DFO as a treatment strategy for acute iron overdose is discussed in [Chap. 46](#) and for aluminum toxicity in [Chap. 87](#).

HISTORY

The development of DFO (or desferrioxamine B) resulted from an analysis of the iron containing metabolites of a species of actinomycetes. Ferrioxamine is a brownish-red compound containing trivalent iron (ferric, Fe³⁺) and three molecules of trihydroxamic acid isolated from the organism *Streptomyces pilosus*.³⁸ DFO is the colorless compound that results when the trivalent iron is chemically removed from ferrioxamine B ([Fig. A7-1](#)).³⁸

FIGURE A7–1. Ferrioxamine.

PHARMACOLOGY

Chemistry

DFO is a water-soluble hexadentate chelator with a molecular weight of 561 Da. The commercial formulation is the mesylate salt with a molecular weight of 657 Da. One mole of DFO binds 1 mole of Fe^{3+} ; therefore, 100 mg DFO as the mesylate salt theoretically can bind 8.5 mg Fe^{3+} .

DFO has a much greater affinity constant for iron (10^{31}) and aluminum (10^{22}) than for zinc, copper, nickel, magnesium, or calcium (10^2 – 10^{14}).³⁸ Thus, at physiologic pH, DFO complexes almost exclusively with ferric iron.^{28,84}

Related Chelators

Deferiprone, a bidentate oral iron chelator with a molecular weight of 139 Da, was approved by the US Food and Drug Administration (FDA) in 2011 for the treatment of iron overload in patients with thalassemia in whom current treatment is inadequate.²⁴ Three moles of deferiprone are required to bind one mole of ferric ion to form a stable complex, which is excreted in the urine.³² Inappropriate ratios of drug to iron may be ineffective or even harmful because of the formation of potentially toxic intermediates.³² Preliminary animal studies of the use of deferiprone in acute iron toxicity are contradictory.^{10,23,36,39} A dose of 75 mg/kg deferiprone produces 60% of the total iron excretion that can be achieved with 50 mg/kg DFO. All of the iron eliminated with deferiprone occurs in the urine, while DFO eliminates iron in the urine and feces.⁴² It has been proposed that deferiprone is less likely to cause toxicity in patients with low iron stores because it can exchange iron with transferrin. Adverse events include QT prolongation, elevation of hepatic enzymes, gastrointestinal effects, arthralgia, chromaturia. Because of embryofetal toxicity in animals studies it is given an FDA pregnancy category D; DFO also carries a boxed warning for agranulocytosis.²⁴ Deferiprone is now being combined with DFO because studies demonstrate additive or synergistic effects in chronic iron overload syndromes. It is hypothesized that deferiprone, because of its smaller size, can enter and chelate cardiac iron and then transfer it to DFO for elimination.⁴²

Deferasirox, an oral iron chelator that was FDA approved in 2005, is indicated to treat chronic iron overload caused by blood transfusions or in patients with thalassemia and elevated liver iron concentrations. Deferasirox, a tridentate ligand with a molecular weight of 373 Da, binds ferric iron in a 2:1 ratio. Deferasirox is lipid soluble with high protein binding (~99%). Once bound to iron, the complex is predominantly eliminated in the feces. The serum half-life (19 ± 6.5 hours) is considerably longer than DFO and deferiprone (47–137 minutes). Preliminary studies demonstrate a comparable efficacy to DFO in patients with chronic iron overload.⁸⁰ One study utilizing deferasirox in a human model of supraphysiologic iron ingestion demonstrated a reduction in serum iron concentrations when compared with placebo.²⁹ However, the dose of iron ingested was 5 mg/kg, and concerns about achieving the effective dose ratio of deferasirox to iron of 2:1 and the effects of acidemia on the binding of deferasirox to iron in a large overdose limit its use in acute iron poisoning at this time.⁵⁶ In addition, similar to other oral chelators, concerns exist about increasing oral absorption of the deferasirox iron complex, and the toxicity of this complex in the setting of an acute iron overdose.^{22,63,72} Adverse events include boxed warnings for gastrointestinal hemorrhage, kidney failure, and hepatic failure. Advanced age increases these risks.²²

Mechanism of Action

DFO binds Fe^{3+} at the 3 N–OH sites, forming an octahedral iron complex (Fig. A7–1). Once bound, the resultant ferrioxamine is very stable. DFO appears to benefit iron-poisoned patients by chelating free iron (non-transferrin plasma iron), iron in transit between transferrin and ferritin (labile chelatable iron pool),^{32,46,65} and hemosiderin and ferritin, while not directly affecting the iron of transferrin, hemoglobin, and cytochromes.^{20,38} Although in vitro studies suggest that DFO removes iron from ferritin and transferrin with only very little from hemosiderin,⁵¹ in vivo experiments demonstrate that DFO cannot remove iron after the iron is bound to transferrin.⁴ DFO does bind “free iron,” now referred to as non-transferrin bound iron found in the plasma after transferrin saturation, which only occurs acutely after overdose or chronically in iron overload syndromes.³² In vitro studies demonstrate that DFO chelates and inactivates cytoplasmic, lysosomal, and probably mitochondrial iron, preventing disruption of mitochondrial function and injury.^{27,46} An in vitro study suggests that DFO gains access to cytosol and endosomes through endocytosis rather than passive diffusion.²⁷ In chronic iron overload, DFO chelates iron deposited in the reticuloendothelial cells found in the spleen, liver, and bone marrow and excretes iron in the urine as ferrioxamine.³² Whether DFO actually chelates the iron within the reticuloendothelial cells or after liberation into the plasma is unclear. In vitro studies demonstrate that the liver can donate iron to DFO; thus, chelation may also subsequently lead to biliary iron excretion and fecal elimination.^{32,50}

Pharmacokinetics/Pharmacodynamics

The volume of distribution of DFO ranges from 0.6 to 1.33 L/kg.^{38,43,59} Because DFO is water soluble, entry into most cells is limited except for hepatocytes, in which facilitated uptake takes place.^{62a,63} The initial distribution half-life of DFO is 5 to 10 minutes.^{41,71} The terminal elimination half-life of DFO is approximately 6 hours in healthy patients² but approximately 3 hours in patients with thalassemia. DFO is metabolized in the plasma to several metabolites (A–F), of which metabolite B is believed to be toxic.^{38,43,59,61} Unchanged DFO undergoes glomerular filtration and tubular secretion.⁵⁰

By comparison, ferrioxamine has a smaller volume of distribution than DFO. In nephrectomized dogs, the volume of distribution of ferrioxamine was calculated to be 19% of body weight compared with 50% of body weight for DFO.³⁸ This finding implies that DFO has a more extensive tissue distribution. The different pharmacokinetic patterns may be related to the potential for facilitated penetrance of the straight-chain molecule DFO compared with that of the octahedral ferrioxamine.⁶¹ Experiments in dogs with normal kidney function demonstrate that intravenous (IV) ferrioxamine is entirely eliminated by the kidney within 5 hours via glomerular filtration and partial reabsorption.^{36,50}

The pharmacokinetics of DFO and ferrioxamine differ in healthy compared with iron overloaded patients. Whereas plasma DFO concentrations in healthy patients are approximately twice the concentrations noted in patients with thalassemia major, ferrioxamine concentrations are five times greater in patients with thalassemia major compared with healthy patients.^{38,73} The metabolism of DFO is unclear but occurs in the plasma by plasma enzymes and in the liver.²⁰

DFO is hemodialyzable. Some investigators suggest that DFO can be administered during hemodialysis to remove ferrioxamine.⁸⁵ Hemodialysis,^{14,71} particularly high flux hemodialysis⁷⁸ and hemoperfusion,¹⁴ are effective in ferrioxamine removal and are indicated in patients with renal failure.

ROLE IN IRON TOXICITY

Due to the limitations in the amount of iron which DFO can chelate, aggressive gastrointestinal decontamination and supportive measures should accompany its use in iron overdose, as discussed in [Chap. 46](#).

Animal Studies

Guinea pigs given oral lethal doses of ferrous sulfate and oral DFO in a dose calculated to bind most of the iron showed dramatically improved survival rates.⁵¹ Mortality rates in this study and in a swine study¹⁹ directly correlated with the delay to DFO administration.⁵¹

In two canine studies, dogs that received the iron–DFO complex orally had a 40% to 100% mortality.^{84,85} When both oral and IV DFO were administered, the mortality rate was 67%.⁸³ A similar follow-up study demonstrated a 50% mortality rate in dogs given a lethal dose (225 mg/kg) of iron, followed by oral DFO (2.6 g) and IV DFO (0.75–1.5 mg/kg/min for 8–12 hours).⁸⁵ These studies discouraged further investigation in the use of oral DFO despite the more favorable results in other animal models.^{5,34,51,77}

Early Human Use and History of Dosing Recommendations

In one of the earliest case series, 172 hemodynamically stable children who were not severely poisoned were treated with 5 to 10 g oral DFO and either 1 or 2 g intramuscular (IM) DFO every 3 to 12 hours.⁸³ Patients who were in shock or severely ill received 1 g of DFO IV at a maximum of 15 mg/kg/h every 4 to 12 hours for 2 to 3 days as necessary. Of the 28 patients who developed coma, shock, or both, three died. One of the three patients who died had received late treatment with DFO.

This case series was expanded to 472 patients, and guidelines for DFO dosing were formulated as a result of this clinical experience.⁸² The recommended initial dose of DFO was suggested as 1 g IM followed by 0.5 g at 4 and 8 hours later and then every 4 to 12 hours as necessary, not to exceed 6 g in 24 hours. For patients in shock, DFO was recommended at an initial dose not to exceed 1 g IV and a rate not to exceed 15 mg/kg/h followed 4 and 8 hours later by two 0.5-g doses for a total dosage not to exceed 6 g in 24 hours. These recommendations for total dosages were not scientifically developed and appear to be based on arbitrary assumptions. However, the manufacturer continues to recommend these doses.²⁰

Intramuscular Versus Intravenous Administration

Prior to 1976, IM DFO was the preferred route of administration, and IV DFO was reserved for patients in shock. However, when transfusion-induced iron overload was studied and IM and IV DFO administration were compared, IV DFO significantly enhanced urinary iron elimination.⁶⁶ This study provided compelling arguments against IM dosing, as did data showing higher peak and more stable DFO concentrations with IV infusions. A single patient was given 425 mg/kg IV

over 24 hours without incident, although the increase in urinary iron excretion seen when the DFO dose increased from 4 to 16 g/day appeared to be of limited consequence.

Duration of Dosing

The optimum duration of DFO administration is unknown. In canine models, serum iron concentrations peak within 3 to 5 hours and then decrease quickly as iron is transported out of the blood into the tissues.^{79,86} In one human study, initial iron concentrations of approximately 500 µg/dL decreased to approximately 100 µg/dL within 12 hours.⁴⁴ Other case reports also suggest that most of the easily accessible iron is distributed out of the blood compartment by 24 hours.²¹ Although severely poisoned patients have received DFO for more than 24 hours, pulmonary toxicity is associated with prolonged DFO infusions.^{31,57,75} Intuitively, in patients with acute iron overdose, DFO should be administered early and for a shorter duration while the iron is easily accessible in the blood. In patients with chronic iron overload, prolonged infusions of smaller DFO doses are necessary to act as a sink and to slowly remove iron from the limited labile pool and tissue stores.³⁵

ROLE IN ALUMINUM TOXICITY

Patients with severe chronic kidney disease are at high risk for aluminum toxicity.⁸⁸ Acute aluminum toxicity resulting from bladder irrigations with alum for hemorrhagic cystitis is also reported.⁶⁰ Chronic aluminum toxicity is reported from administration of aluminum salts as phosphate binders or from hemodialysis with a water source containing aluminum. DFO binds aluminum to form aluminoxamine, analogous to iron and ferrioxamine. The chelate is a 1:1 octahedral complex with aluminum.⁸⁸ Aluminoxamine is renally excreted. In patients with kidney insufficiency, hemodialysis (especially with a high-flux membrane) is effective in removing the aluminoxamine and should be used to prevent aluminum redistribution to the central nervous system and other tissues.⁵³ The dosing of DFO is unclear but should be tailored to the patient's serum aluminum concentrations, symptoms, and response.⁵³ Electroencephalography monitoring is recommended. DFO doses of 5 to 15 mg/kg/day, infused over several hours and 6 to 8 hours before a 3 to 4 hour run of high flux hemodialysis, have been successful and maximize aluminoxamine removal without exacerbating adverse events.^{53,68} The appropriate duration of this DFO dosing with hemodialysis is unknown and should be based on central nervous system symptoms, serum aluminum concentrations, and kidney function. The correlation of serum aluminum concentrations with toxicity is poorly defined and may depend on the chronicity of aluminum exposure. Patients are treated for days to weeks, with one holiday per week (Chap. 87).

ADVERSE EFFECTS

DFO administration to patients with acute iron overdose is associated with rate related hypotension, hypersensitivity reactions and systemic allergic reactions, pulmonary toxicity, and infection. DFO administration to patients with chronic iron overload is associated with auditory, ocular, and pulmonary toxicity and infection.^{9,35}

Significant hypotension was first noted in 1965 in two children who were administered approximately 80 to 150 mg/kg DFO IV over 15 minutes.⁸⁴ The mechanism for rate-related hypotension is not fully understood, although histamine release is at least partially implicated. Although elevated histamine concentrations were documented in a canine experiment, pretreatment with diphenhydramine was not protective.⁸⁵ Intravascular volume depletion caused by iron toxicity also contributes to hypotension. No experiment has determined the maximum safe rate of DFO administration. Adverse events of DFO, including tachycardia, hypotension, and shock, were reported with rapid infusion.⁸³ These complications resulted in the current recommendations for less rapid IV infusions of DFO not to exceed 15 mg/kg/h.^{83–85} Currently suggested IV infusion rates are somewhat empirical because of the lack of robust evidence. Higher rates were administered successfully in critically ill patients when time was of the essence.^{11,15,21}

Acute respiratory distress syndromes (ARDS) occur in patients with acute iron overdoses who have received IV administration of DFO (15 mg/kg/h) therapy for more than 24 hours.^{3,37,75} Usually, iron concentrations are normal in these patients within 24 hours, and the rationale for continued administration of DFO was not reported. Examination of the nontoxicologic literature reveals other instances of ARDS occurring in patients receiving continuous IV DFO for hemosiderosis and malignancies.^{13,25,81} Administration of continuous IV doses of DFO for prolonged (>24 hours) periods was common to all of these patients. The mechanism for development of pulmonary toxicity after DFO is unknown. Pulmonary toxicity may result from excessive DFO chelation of intracellular iron and depletion of catalase, resulting in oxidant damage,³⁰ or generation of free radicals.¹

DFO therapy may lead to infection with a number of unusual organisms, including *Yersinia enterocolitica*, *Zygomycetes* spp, and *Aeromonas hydrophilia*. The virulence of these organisms is facilitated when the DFO–iron complex acts as a

siderophore for their growth.^{45,49,52} Most cases of septicemia occurred when DFO was used for treatment of aluminum toxicity in patients receiving chronic hemodialysis.⁵⁰ Several cases of *Yersinia* sepsis were reported after acute iron overdose and treatment with DFO.^{49,52}

Ocular toxicity characterized by decreased visual acuity and peripheral visual fields, night blindness, color blindness, and retinal pigmentary abnormalities has occurred in patients who received continuous IV DFO for thalassemia and other nonacute iron and aluminum excess conditions.^{8,12,18,55,58} Ototoxicity documented by abnormal audiograms indicating partial or total deafness is reported.^{61,62} However, neither ocular toxicity nor ototoxicity is reported in the setting of acute overdose treatment. When DFO is used in the absence of iron overload, zinc deficiency and decreases in serum ferritin, mean corpuscular volume and hemoglobin may develop.⁴⁰

Infusion pump malfunctions have occasionally led to acute kidney injury (AKI) due to IV DFO overdose. This has been successfully treated with hemodialysis after failure of medical management.¹⁶ One inadvertent overdose of IV DFO in a patient with severe iron overload associated with sickle cell β thalassemia resulted in AKI within 12 to 18 hours of IV DFO administration. The patient received a planned 45 g (700 mg/kg) 96 hour infusion over 8 hours due to incorrect programming of the infusion pump. High efficiency hemodialysis, instituted after an 8 hour trial of intravenous hydration and mannitol were unsuccessful in restoring kidney function.⁶⁴

PREGNANCY AND LACTATION

A review of the literature identified 61 cases of intentional iron overdose in pregnant women.⁷⁶ Serious iron toxicity with organ involvement was associated with spontaneous abortion, preterm delivery, and maternal death. There is no evidence to indicate that DFO is teratogenic.⁷⁶ Neither iron nor DFO appears to cross the ovine placenta.¹⁷ A case report of a pregnant woman with thalassemia and a review of 40 other pregnant patients with thalassemia treated extensively with DFO found no evidence of teratogenicity.⁶⁹ Thus, DFO should be administered to pregnant women with acute iron overdose for the same indications as for nonpregnant women and is listed as FDA pregnancy category C. Excretion in breast milk is not reported.

DOSING AND ADMINISTRATION

The indications and dosage schedules for DFO administration are largely empirical.^{6,67} Systemic toxicity associated with acute iron poisoning manifested by coma, shock, or metabolic acidosis warrants IV infusion of DFO. The duration of therapy probably should be limited to 24 hours to maximize effectiveness while minimizing the risk of pulmonary toxicity. Some investigators have suggested that more than the recommended dose of 15 mg/kg/h be infused during the first 24 hours for life-threatening iron toxicity, but this recommendation remains to be validated experimentally.³⁵ We recommend starting with 5 mg/kg/h and increasing after 15 minutes if tolerated to 15 mg/kg/h to minimize the risk of hypotension. In adults, after the first 1000 mg is infused, the subsequent doses can be adjusted to infuse the remainder of the 6 to 8 g during the next 23 hours. How exactly this should be done is not clear. Theoretically, an adult patient with significantly elevated serum iron concentrations (>1000 $\mu\text{g/dL}$) who is severely symptomatic, might do better with continuing at a rate of 15 mg/kg/h if tolerated for the first several hours and then reducing the dose to limit the total 24 hours dose to 6 to 8 g. If after the first 1000 mg the patient improved clinically then consideration might be given to administering the remainder of the 5 g over the next 23 hours. In a 70 kg patient, this would be about 3 to 4 mg/kg/h for the next 23 hours. Dosing in obese patients is unknown; however, because DFO is water soluble, limiting the hourly dose in obese adults to 1000 mg is reasonable. The manufacturer recommends not exceeding 125 mg/h after the first 1000 mg has been infused. Although patients with mild toxicity can be treated with IM injections of 90 mg/kg of DFO (maximum of 1 g in children or 2 g in adults), this volume of antidote cannot be given IM with ease or painlessly in children. Therefore, few clinicians administer IM DFO, with most preferring the IV route ([Chap. 46](#)). The total daily parenteral dose is limited by the infusion rate in children (if the manufacturer's recommendations are followed). Conservative recommendations in adults limit the dose to 6 to 8 g/day, although doses as high as 16 g/day with diverse dosing regimens have been administered without incident.^{15,21,47,57,66,74}

URINARY COLOR CHANGE

To further define the role of DFO and the quantitative excretion of urinary iron, investigators studied urinary samples.⁵¹ Several reviews of patients with acute iron poisoning who had received DFO^{48,87} investigated the correlation between urinary iron concentrations and systemic toxicity. Most data suggest that the absence of a urine color change, often referred to as a vin rose color, after DFO administration indicates very little renal excretion of ferrioxamine.²⁶ However, unless a baseline urine color is obtained before DFO administration, post-DFO administration comparisons of urine color are unreliable. DFO administration may not yield a vin rose color despite severe iron toxicity and/or high serum iron

concentrations.⁷⁰ No relationship between urinary iron excretion, clinical iron toxicity, and the effectiveness of DFO has been established.

FORMULATION AND ACQUISITION

DFO mesylate (Desferal) is available in vials containing 500 mg or 2 g of sterile, lyophilized powder.²⁰ Adding 5 or 20 mL of sterile water for injection to either the 500 mg or the 2 g vial, respectively, results in an approximately 100 mg/mL solution. The drug must be completely dissolved before using. The resulting solution is isotonic, clear, and colorless to slightly yellowish²⁰ and can be diluted further with 0.9% NaCl solution, glucose in water, or Ringer lactate solution for IV administration. For IM administration, a smaller volume of solution is preferred. Adding 2 or 8 mL of sterile water for injection to the 500 mg or 2 g vial, respectively, results in a stronger yellow-colored solution containing approximately 200 mg/mL.

SUMMARY

- DFO is the parenteral chelator of choice for treatment of iron poisoning.
- No controlled studies have evaluated its efficacy or dosing.
- IV is the preferred route of administration.
- Early administration captures iron still in the blood compartment.
- Administration for more than 24 hours after ingestion may predispose to acute respiratory distress syndrome.
- DFO is also used for chelation of aluminum in patients with chronic kidney failure.

47 VITAMINS

Beth Y. Ginsburg

Vitamins are essential for normal human growth and development.⁴⁹ By definition, a vitamin is a substance present in small amounts in natural foods, is necessary for normal metabolism, and whose lack in the diet causes a deficiency disease.⁴²

A standard North American diet is sufficient to prevent overt vitamin deficiency diseases.^{68,77} However, suboptimal vitamin status is common in Western populations and can be a risk factor for chronic diseases such as cardiovascular disease, cancer, and osteoporosis.^{68,77} Groups at particular risk include the elderly, the hospitalized, alcohol-dependent individuals, pregnant women, and others with poor nutritional status. The American Dietetic Association posits that the best strategy for promoting optimal health and reducing chronic disease is to choose a wide variety of nutrient-rich foods, while the use of supplements can help some people meet their nutritional needs.¹⁵⁴ Health care professionals should identify patients with poor nutrition or other reasons for increased vitamin needs and offer guidance on vitamin supplementation. Some suggest that since most people do not consume an optimal amount of vitamins by diet alone, it is prudent for all adults to take vitamin supplements with physician guidance.^{68,77}

Dietary supplement use has increased over time in the United States. National Health and Nutrition Examination Survey (NHANES) data collected from 2003 to 2006 demonstrate that dietary supplement use was reported by 49% of the population age 1 year and older, an increase of approximately 10% from NHANES data from 1988 to 1994, with 79% of users taking them daily for the past 30 days.¹⁵ The categories of dietary supplements included multivitamin, multiminerals (MVMMs), botanicals, and amino acids. Among adults and children, MVMMs were the most commonly reported dietary supplement, with 33% of the population reporting use.

Unfortunately, many individuals share the mistaken beliefs that vitamin preparations provide extra energy or promote muscle growth and regularly ingest quantities of vitamins in great excess of the recommended dietary allowances (RDAs) (Table 47–1). The most commonly used MVMM preparations generally do not exceed 100% of the RDA, but excessive vitamin intake is more likely to occur in MVMM users who also take single vitamin supplements.¹⁹⁹ Excess vitamin intake may also occur in individuals taking an MVMM who ate a healthy diet that included fortified foods and beverages.¹⁶⁸ Some vitamins are associated with consequential adverse effects when ingested in very large doses. Adverse events also may be associated with the use of some vitamins at the RDA or at amounts less than or approaching the established tolerable upper intake level (UL) in certain populations. Those who smoke should avoid products containing large amounts of vitamin A and β -carotene because studies have linked use of these vitamins to an increased risk of lung cancer in smokers.¹⁹⁰ In one study, smokers taking 20 mg/day of β -carotene (UL 36 mg/day) had an 18% higher lung cancer rate than smokers taking a placebo.²²⁴ Individuals taking medications to reduce blood clotting, such as warfarin, should not take supplemental vitamin K since it is involved in blood clotting and may reduce the effectiveness of warfarin and similar medications.

TABLE 47–1. Recommended Dietary Daily Allowances/Adequate Daily Intakes

Age (years)	Vitamin A (μg RAE/1U)	Vitamin D ($\mu\text{g}/10\text{U}$) ^a	Vitamin E (mg α -TA/1U)	Vitamin C (mg)	Vitamin B ₁ (mg)	Niacin (mg NE) ^a
Infants						
0.0–0.5	400/1300 ^a	5/200 ^a	4/4 ^a	40 ^a	0.1 ^a	2 ^a

Vitamins can be divided into two general classes. Most of the vitamins in the water-soluble class have minimal toxicity because they are stored to only a limited extent in the body. Thiamine, riboflavin, cyanocobalamin, pantothenic acid, folic acid, and biotin are not reported to cause any toxicity following oral ingestion.⁴⁹ Ascorbic acid (vitamin C), nicotinic acid (vitamin B₃), and pyridoxine (vitamin B₆) have associated toxicity syndromes. However, the fat-soluble vitamins can bioaccumulate to massive degrees. As a result, the potential for toxicity greatly exceeds that of the water-soluble group. Vitamins A, D, and E (but not K) are associated with toxicity following very large overdose or chronic overuse. The adverse effect secondary to vitamin K is limited to severe, and sometimes fatal, anaphylactoid reactions with rapid administration of the intravenous (IV) preparation.⁷⁵

VITAMIN A

MW = 272.43 Da
 Therapeutic serum concentration = 65–275 IU/dL
 16.6–83.3 µg/dL

History and Epidemiology

Two independent groups discovered vitamin A in 1913.^{157,178} They reported that animals fed an artificial diet with lard as the sole source of fat developed a nutritional deficiency characterized by xerophthalmia. They found that this deficiency could be corrected by adding to the diet a factor contained in butter, egg yolks, and cod liver oil. They named the substance “fat soluble vitamin A.” The chemical structure of vitamin A was determined in 1930.¹²³ Vitamin A is also found naturally in liver, fish, cheese, and whole milk. In the United States and other parts of the world, including some developing countries, many cereal, grain, dairy, and other products, as well as infant formulas, are fortified with vitamin A.^{6,240}

Vitamin A toxicity can occur in people who ingest large doses of preformed vitamin A in their daily diets. Inuits in the sixteenth century recognized that ingestion of large amounts of polar bear liver caused a severe illness characterized by headaches and prostration.⁷⁶ Arctic explorers in the 1800s knew of the poisonous qualities of polar bear liver and described an acute illness following its ingestion.⁸⁵ Explorers also described a condition among the Inuit population known as pibloktoq, or “Arctic hysteria,” characterized by hysteria, depression, echolalia, insensitivity to extreme cold, and seizures, and believed to be related to ingestion of polar bear liver and other organ meats.¹⁸² Vitamin A toxicity is implicated in the etiology of pibloktoq as some somatic and behavioral effects of vitamin A toxicity closely parallel many of the symptoms reported in Inuit patients diagnosed with pibloktoq.¹³² However, the toxic substance in polar bear liver was not identified as vitamin A until 1942.²⁰⁰ The vitamin A content of polar bear liver is as high as 34,600 IU/g (10,400 RAE/g), supporting the view that vitamin A is the toxic factor in liver.²⁰³

Vitamin A toxicity was reported in an adult who chronically ingested large amounts of beef liver,¹¹⁴ as well as following ingestion of the liver of the grouper fish *Cephalopholis boenak*, which has a high content of vitamin A.⁴³ Ingestion of whale and seal liver, as well as the livers of large fish, such as shark, tuna, and sea bass, also is associated with development of vitamin A toxicity.

Vitamin A toxicity usually is not expected to occur following ingestion of large doses of provitamin A carotenoids. Vitamin A induced hepatotoxicity and neurotoxicity was believed to have developed in an 18 year-old girl who maintained a diet nearly limited to foods rich in the carotenoid β -carotene, including pumpkin, carrots, and laver (nori), for several years.¹⁷⁰ However, she also included an unspecified, although reportedly small, amount of fish, red meat, and liver in her diet.

Vitamin A toxicity is rare, with a reported average incidence of less than 10 cases per year from 1976 to 1987.²⁰ The majority of reported cases of vitamin A toxicity result from inappropriate use of vitamin supplements.^{17,20} In the United States, 28% of the population report taking a dietary supplement containing vitamin A.¹⁵

Vitamin A is present in two forms. Preformed vitamin A as retinol is derived from retinyl esters, its storage form, in animal sources of food. Provitamin A carotenoids are vitamin A precursors and are found in plants. Among the carotenoids, β -carotene is most efficiently made into retinol. The term vitamin A was classically only used to refer to the compound retinol. Currently, it is used to describe all retinoids, compounds chemically related to retinol that exhibit the biological activity of retinol. Retinol can be converted in the body to the retinoids retinal and retinoic acid. Synthetic retinoids have been developed via chemical modification of naturally occurring retinoids, often for a specific therapeutic purpose. Vitamin A activity is expressed in retinol activity equivalents (RAEs). One RAE corresponds to 1 µg of retinol or 3.33 IU of vitamin A activity as retinol. One RAE also corresponds to 12 µg of β -carotene.

Vitamin A content varies widely among different food types. A 3 oz serving of cooked beef liver contains 30,325 IU (9100 RAE) of vitamin A, whereas 1 cup of whole milk contains 305 IU (92 RAE) of vitamin A. Fish-liver oils, such as swordfish and black sea bass, have extremely large amounts of vitamin A and may contain more than 180,000 IU (54,050 RAE) of vitamin A per gram of oil. Carotenoids are present in yellow and green fruits and vegetables. A raw carrot has a high β -carotene content of approximately 20,250 IU (6080 RAE). One half cup serving of spinach contains approximately 7400 IU (2220 RAE) of β -carotene, whereas an apricot or peach contains 500 to 600 IU (150–180 RAE). The average American diet provides about one half of its daily vitamin A intake as carotenoids and about one half as preformed vitamin A.⁴⁶ The RDA of vitamin A is 900 µg RAE/day (3000 IU/day) for adult men and 700 µg RAE/day (2300 IU/day) for women (Table 47–1).⁸⁰ The UL for adults is 3000 µg RAE/day (9900 IU/day).

As a group, retinoids have specific sites of action and varying degrees of biologic potency. Retinoic acid is primarily responsible for maintaining normal growth and differentiation of epithelial cells in mucus secreting or keratinizing tissue.¹⁵³ Vitamin A deficiency results in the disappearance of goblet mucous cells and replacement of the normal epithelium with a stratified, keratinized epithelium. Dermal manifestations are the earliest to develop and include dry skin and hair and broken fingernails. In the cornea, hyperkeratization is called xerophthalmia and can lead to permanent blindness. Alterations in the epithelial lining of other organ systems may lead to increased susceptibility to respiratory infections, diarrhea, and urinary calculi. Vitamin A, in the form of 11-cis-retinal, plays a critical role in retinal function.²³⁴ Deficiency results in nyctalopia, which is decreased vision in dim lighting, more commonly known as night blindness.

Vitamin A is prescribed for some people for dermatologic and ophthalmic conditions. Vitamin A toxicity often occurs in adults who continue to use the vitamin without medical supervision.⁸⁶

Isotretinoin (Accutane), 13-cis-retinoic acid, is prescribed for treatment of severe cystic acne. Of great concern is the teratogenicity associated with its use by pregnant women. There has not been any association between male use of isotretinoin during the time of conception and birth defects. The iPLEDGE program is a mandatory US Food and Drug Administration (FDA) risk evaluation and mitigation strategy for the distribution of isotretinoin that was initiated in 2006. Its goals are to inform prescribers, pharmacists, and patients about the serious risks of isotretinoin's and safe-use conditions and to prevent fetal exposure to isotretinoin.²²⁸ Components of the program include mandatory enrollment, documentation of a negative pregnancy test and birth control use, and prescriber, pharmacist, and patient education. The iPLEDGE program replaced the FDA's System to Manage Accutane-Related Teratogenicity (SMART) program that was initiated in 2002. Although both programs share many features, the SMART program was voluntary and did not include mandatory record keeping or reporting. A review after the implementation of the SMART program revealed that there was an increase in the number of pregnant women prescribed isotretinoin compared with the previous year. The review revealed that prescribers were not providing adequate patient education regarding the risk of teratogenicity and that there was not compliance with essential portions of the pregnancy prevention program.¹⁹⁸

All-trans-retinoic acid (ATRA), or tretinoin, is used as a differentiating chemotherapeutic in the treatment of acute promyelocytic leukemia (APL), a disease characterized by the accumulation of promyelocytic blasts in bone marrow due to obstruction of differentiation of granulocytic cells.¹³⁵ ATRA, in combination with anthracycline chemotherapy, improves the complete remission rate, often reported to be greater than 90%, and reduces the incidence of relapse to only 10% to 15% when used as maintenance therapy.⁷¹ APL differentiation syndrome (DS), previously known as ATRA syndrome or retinoic acid syndrome, is the main adverse effect and occurs in up 14% to 16% of patients who receive ATRA with an associated mortality of about 2%.¹⁸⁴ ATRA has also been used for the treatment of myelodysplastic syndrome and acute myelogenous leukemia.

Pharmacology, Pharmacokinetics, and Toxicokinetics

Absorption of vitamin A in the small intestine is nearly complete. However, some vitamin A may be eliminated in the feces when large doses are taken. The majority of vitamin A is ingested as retinyl esters, the storage form of retinol.¹⁵³ Retinyl esters undergo enzymatic hydrolysis to retinol by digestive enzymes in the intestinal lumen and brush border of the intestinal epithelial wall. A small portion of retinol is absorbed directly into the circulation, where it is bound to retinol-binding protein (RBP) and transported to the liver. Most of the retinol is taken into intestinal epithelial cells by RBP.¹⁷⁵ Subsequently, retinol is reesterified and incorporated into chylomicrons, which are released into the blood and taken up by the Ito cells of the liver. After large oral doses, significant amounts of retinyl esters coupled to chylomicrons circulate in association with low-density lipoprotein (LDL) and are delivered to the liver. Approximately 50% to 80% of the total vitamin A content of the body is stored in the liver as retinyl esters.²⁸ The liver releases vitamin A into the bloodstream to maintain a constant plasma retinol concentration and is thus delivered to tissues as needed.

Carotenoid absorption requires bile and absorbable fat in the stomach or intestine. These components combine with carotenoids to form mixed lipid micelles which move into the duodenal mucosal cells via passive diffusion. The majority of β -carotene that is metabolized undergoes central cleavage via oxidation to form retinal, which is then reduced to retinol. Retinol is then esterified with fatty acids and incorporated into chylomicrons, which are transported to the bloodstream via the lymphatics for delivery to the liver. Massive doses of β -carotene are rarely associated with vitamin A toxicity due to decreased efficiency in absorption secondary to saturation of dissolution in bulk lipid, micellar incorporation, and diffusion due to a reduction in the concentration gradient.¹⁸¹ Unabsorbed β -carotene is excreted in the feces. In addition, there is a decrease in the rate of conversion of carotenoids to vitamin A.⁶³ Hypercarotenemia develops when massive doses are ingested. Excess absorbed β -carotene is incorporated with lipoproteins and released into the bloodstream via the lymphatics for delivery to the adipose tissue and adrenals for storage. Hypercarotenemia usually is not associated with morbidity.

The normal serum retinol concentration is approximately 30 to 70 $\mu\text{g/dL}$.²¹⁴ These concentrations are maintained at the expense of hepatic reserves when insufficient amounts of vitamin A are ingested. A normal adult liver contains enough

vitamin A to fulfill the body's requirements for approximately 2 years.¹⁶³ Excessive intake of vitamin A is not initially reflected by elevated serum concentrations because vitamin A is soluble in fat but not in water. Instead, hepatic accumulation is increased. This storage system allows for cumulative toxic effects. Although no quantitative relationship exists between the magnitude of liver stores and serum concentrations of vitamin A, in chronic vitamin A toxicity serum concentrations are generally higher than 3.49 $\mu\text{mol/L}$ (95 $\mu\text{g/dL}$).²⁰ Vitamin A has a half-life of 286 days.^{216,238} Retinoids undergo a variety of metabolic and conjugation pathways and are subsequently eliminated in the feces, urine, or bile.

Clinical toxicity correlates well with total body vitamin A content, which is a function of both dose and duration of administration. A randomized double blind trial, in which 390 women received 400,000 IU (120,000 RAE) of vitamin A as a single dose were compared with 380 women who received placebo, suggested that dosing at this level is well tolerated.¹¹³ Doses of 100,000 IU (30,000 RAE) of vitamin A in infants aged 6 to 11 months and 200,000 IU (60,000 RAE) of vitamin A every 3 to 6 months for infants and children aged 12 to 60 months result in few adverse events.¹⁹ The minimal dose required to produce toxicity in humans is not established. However, an animal study has shown that the median lethal acute dose in monkeys is 560,000 IU (168,000 RAE) per kilogram of body weight.¹⁴⁸ In this study, all monkeys receiving more than 300,000 RAE/kg (999,000 IU/kg) died, whereas none died at a dose of 100,000 RAE/kg (333,000 IU/kg). Hepatotoxicity can occur in humans following an acute ingestion of a massive dose of vitamin A (>600,000 IU {180,000 RAE}).¹²⁹

Vitamin A toxicity may occur more frequently secondary to chronic ingestions of vitamin A. Hepatotoxicity typically requires vitamin A ingestions of at least 50,000 to 100,000 IU/day (15,000–30,000 RAE/day) for months or years.^{6,129} One study found that in patients with vitamin A–induced hepatotoxicity, the average daily vitamin A intake was higher in patients who developed cirrhosis (135,000 IU/day 40,500 RAE/day) compared with patients who developed noncirrhotic liver disease (66,000 IU/day 20,000 RAE/day).⁸⁴ However, case reports have documented hepatotoxicity resulting from vitamin A doses as low as 25,000 IU/day (7500 RAE/day),^{86,129} a dose widely available in nonprescription vitamin A preparations.

Pathophysiology

The mechanism of action for many of the toxic effects of vitamin A may be at the nuclear level. Retinoic acid influences gene expression by combining with nuclear receptors.¹⁵³ Retinoids also influence expression of receptors for certain hormones and growth factors. Thus, they are able to influence growth, differentiation, and function of target cells.¹⁴⁵

In epithelial cells and fibroblasts, retinoids affect changes in nuclear transcription, resulting in enhanced production of proteins such as fibronectin and decreased production of other proteins such as collagenase.¹⁵⁰ Excessive concentrations of retinoids where goblet cells are present lead to the production of a thick mucin layer and inhibition of keratinization. In addition, lipoprotein membranes have increased permeability and decreased stability, resulting in extreme thinning of the epithelial tissue.

In vitro studies in bone demonstrate that high doses of vitamin A are capable of directly stimulating bone resorption and inhibiting bone formation. This effect is secondary to increased osteoclast formation and activity and inhibition of osteoblast growth.^{172,177,209}

Hepatotoxicity may develop secondary to a single large acute overdose or ingestion of smaller doses if taken over a prolonged time.^{86,129} A total of 90% of hepatic vitamin A stores are located in the Ito, or fat-storing, cells of the liver, which are located in the perisinusoidal space of Disse, and are responsible for maintaining normal hepatic architecture.^{99,100} Ito cells undergo hypertrophy and hyperplasia as vitamin A storage increases.¹²⁹ This results in transdifferentiation of the Ito cell into a myofibroblastlike cell that secretes a variety of extracellular matrix components, leading to narrowing of the perisinusoidal space of Disse, obstruction to sinusoidal blood flow, and noncirrhotic portal hypertension (Fig. 47–1).^{54,91,110,124,129,206} Continued ingestion of vitamin A and hepatic storage may lead to obliteration of the space of Disse, sinusoidal barrier damage, perisinusoidal hepatocyte death, fibrosis, and cirrhosis^{110,118,129,204} (Chap. 23).

FIGURE 47–1. Schematic demonstration of hepatotoxicity resulting from excessive deposition of vitamin A in the Ito cells of the liver.

Vitamin A toxicity has long been thought to be the cause of the severe headaches and papilledema associated with idiopathic intracranial hypertension (IIH).¹⁹³ Increased concentrations of unbound retinol in the cerebral spinal fluid (CSF) of patients with IIH suggest that vitamin A is involved in the pathogenesis of IIH.^{223,237} However, the mechanisms by which vitamin A leads to increased intracranial pressure (ICP) in IIH are not definitively known.¹⁹³ Unbound, circulating retinol and retinyl esters are proposed to be capable of interacting with cell membranes and producing damage by membranolytic surface-active properties.¹¹⁵ In the central nervous system (CNS), disruption of cell membrane integrity might lead to disruption of CSF outflow, thereby producing signs and symptoms consistent with IIH.^{88,115,127,149} It has also been suggested that vitamin A could lead to intracranial hypertension via enhanced transcription of genes involved in CSF secretion or absorption.⁹² Another explanation for the association of vitamin A with IIH involves the recent recognition of RBP as a signaling molecule altering CSF secretion or absorption.¹⁴²

Clinical Manifestations

Symptoms of an acute overdose of vitamin A often develop within hours to two days after ingestion.¹⁶³ Initial signs and symptoms include headache, papilledema, scotoma, photophobia, seizures, anorexia, drowsiness, irritability, nausea, vomiting, abdominal pain, liver damage, and desquamation.¹⁶³ Nonspecific symptoms include fatigue, fever, weight loss, edema, polydipsia, dysuria, hyperlipidemia, anemia, and menstrual abnormalities.

Hypercarotenemia produces a yellow-orange skin discoloration that can be differentiated from jaundice by the absence of scleral icterus.

Chronic toxicity of vitamin A affects the skin, hair, bones, liver, and brain. The most common skin manifestations include xerosis, which is associated with pruritus and erythema, skin hyperfragility, and desquamation.^{60,61,243} Retinoid toxicity may cause hair thinning and even diffuse hair loss in 10% to 75% of patients.^{79,89,126} In addition, the characteristics of the hair may change after regrowth. Hair sometimes becomes permanently curly or kinky.¹⁰ Nail changes include a shiny appearance, brittleness, softening, and loosening.⁷² Dryness of mucous membranes develops with chapped lips and xerosis of nasal mucosa, which sometimes is associated with nasal bleeding.⁵¹

Findings from epidemiologic studies are consistent with bone loss and a resulting increase in fracture risk. In northern Europe, the region with the highest incidence of osteoporotic fractures, dietary intake of vitamin A is high. A study of this population demonstrated that the risk of first hip fracture was increased by 68% for every 1 mg increase in RAE intake.¹⁵⁹ This study also showed that compared with intake less than 0.5 mg/day, intake greater than 1.5 mg/day reduced bone mineral density by 10% at the femoral neck, 14% at the lumbar spine, and 6% for the total body, doubling the risk of hip fracture. These findings are supported by other studies demonstrating an increased risk of hip fracture among women with

elevated serum vitamin A concentrations and in women ingesting large daily amounts of vitamin A.^{73,176} One study found that among women not taking supplemental vitamin A, a diet rich in vitamin A was also associated with an increased fracture risk.⁷³

Other musculoskeletal findings include skeletal hyperostoses, most commonly affecting the vertebral bodies of thoracic vertebrae, extraspinal tendon and ligament calcifications, soft-tissue ossification, cortical thickening of bone shafts, periosteal thickening, and bone demineralization.^{51,163,165} Many of these findings are apparent on radiographs. Patients often complain of bone and joint pain and muscle stiffness or tenderness. Hypercalcemia, with low or normal parathyroid hormone (PTH) concentrations, likely results from increased osteoclast activity and bone resorption.³⁰ Patients with chronic kidney disease are at increased risk for developing hypercalcemia at vitamin A doses lower than usual toxic doses secondary to decreased renal metabolism of retinol. This complication occurred in an 8 year-old boy with chronic kidney disease following a dose of 12,000 IU/day (3600 RAE/day) for at least 2 years.⁵⁸ Premature epiphyseal closure in children is reported.¹⁸⁹ Teratogenic effects include interference with skeletal differentiation and growth.³⁰

The degree of hepatotoxicity appears to correlate with the dose of vitamin A and chronicity of use. With large doses, cirrhosis develops and may lead to portal hypertension, esophageal varices, jaundice, and ascites.^{55,86,129} Hepatotoxicity may be manifested by elevations in bilirubin, aminotransferases, and alkaline phosphatase concentrations.

Idiopathic intracranial hypertension is characterized by elevated ICP in the absence of a structural anomaly. It occurs in patients with altered endocrine function, systemic diseases, impaired cerebral venous drainage, or ingestion of various xenobiotics, including excessive vitamin A (Table 47–2).⁵ The syndrome is most common in young obese women, but the etiology remains unknown in the majority of cases. The first case of IIH associated with vitamin A toxicity was described in 1954.⁸⁵ However, the symptoms were first described in 1856 by an Arctic explorer who noted vertigo and headache after eating polar bear liver.²¹³ Patients typically present with headache and visual disturbances, including sixth nerve palsies, visual field deficits, and blurred vision, and have a normal mental status. Despite severe papilledema, visual loss often is minimal. However, permanent blindness may result from optic atrophy.¹⁴⁷ Other symptoms of neurotoxicity include ataxia, fatigue, depression, irritability, and psychosis.²⁶

Tubocurarine

Vitamin A

Isotretinoin is effective in the management of acne. However, its use is associated with teratogenicity. It is thought to interfere with cranial neural crest cells, which contribute to the development of both the ear and the conotruncal area of the heart, and may cause malformed or absent external ears or auditory canals and conotruncal heart defects.¹³¹ Although studies have not shown a teratogenic risk with topical preparations, case reports describe fetal malformations associated with topical preparation use during pregnancy.^{13,36,119,143,212} In addition, mucocutaneous abnormalities, IIH, corneal opacities, hypercalcemia, hyperuricemia, musculoskeletal symptoms, liver function abnormalities, elevated triglyceride concentrations, and spontaneous abortion are reported.^{3,78,84,96,97}

Acute promyelocytic leukemia DS is the main adverse effect of treatment with ATRA. The pathophysiology of DS is not well understood, but involves an inflammatory response. Proposed mechanisms include tissue infiltration of APL cells, particularly in the lungs but also in the liver, spleen, and heart, and leukocyte extravasation.¹³³ Onset of symptoms is typically 2 to 21 days after initiation of ATRA.¹⁸⁴ The hallmarks of DS are fever and respiratory distress.^{184,201} Other common signs and symptoms include elevated white blood count, dyspnea, pulmonary edema, pulmonary infiltrates, and pleural and pericardial effusions.^{184,201} Weight gain, bone pain, headache, hypotension, congestive heart failure, acute kidney injury, and hepatotoxicity occur less commonly.^{184,201} There are no established criteria for diagnosis, but some suggest that three signs and symptoms are needed.²⁰¹ Elevated leukocyte counts at diagnosis or rapidly increasing counts during ATRA treatment predict the development of DS. Addition of dexamethasone to the ATRA treatment regimen decreases the incidence of DS to approximately 15% and its mortality to 1%.⁷⁰ However, other data demonstrated a 17% occurrence of DS despite concurrent use of steroids and not all authors support its use.^{184,242}

Diagnostic Testing

The diagnosis of vitamin A associated hepatotoxicity is supported by histologic evidence of Ito cell hyperplasia with fluorescent vacuoles on liver biopsy.⁸⁶ Laboratory testing should also include serum electrolytes including calcium, hepatic enzymes, a complete blood cell count, and a vitamin A concentration. Because the liver has a large storage capacity for excess vitamin A, hepatotoxicity may occur prior to an elevation in the serum concentration of vitamin A, which may be normal or even low, in the setting of an acute overdose. As the hepatic storage capacity is overwhelmed, the serum concentration may rapidly rise in a nonlinear fashion. Further evaluation should be guided by the clinical presentation and may include bone radiographs, computed tomography of the brain, and lumbar puncture.

Treatment

Management of a patient with a recent acute, large overdose should begin with gastrointestinal decontamination. This can be accomplished with a dose of activated charcoal. In extremely large overdoses that are expected to produce significant toxicity, gastric lavage may be considered. Although most signs and symptoms of vitamin A toxicity resolve within one week following vitamin A discontinuation and supportive care, papilledema, desquamation, and skeletal abnormalities may persist for several months. Hypercalcemia should be treated with IV fluids, loop diuretics, and prednisone 20 mg/day.²⁵ Bisphosphonates may be beneficial in refractory cases.

Idiopathic intracranial hypertension may require more aggressive therapy. Indications for treatment include visual field loss and symptoms of elevated ICP.¹⁹³ Acetazolamide, a carbonic anhydrase inhibitor, is the most commonly used treatment for IIH.¹⁹³ It is usually started at a dose of 0.5 to 1 g/day and gradually increased until clinical improvement is seen to 3 to 4 g/day.¹⁹³ Acetazolamide has teratogenic effects in animals and is designated FDA pregnancy category C. Topiramate, a partial carbonic anhydrase inhibitor that is used in the treatment of migraine headaches and epilepsy has demonstrated efficacy comparable to acetazolamide in the treatment of IIH.³⁸ Its adverse effect of weight loss may also be beneficial for patients with IIH. Furosemide is considered second-line treatment, but can be used in patients who cannot tolerate acetazolamide.^{29,193} The role of corticosteroids in the treatment of IIH is controversial and they should not be used chronically for the treatment of papilledema.²⁹ However, a short course of high dose corticosteroids may be used in patients with acute visual loss from fulminant papilledema.¹⁴⁴ Patients with extremely high ICP may benefit from daily lumbar punctures with CSF drainage.

Treatment of DS involves prompt administration of corticosteroids, commonly dexamethasone 10 mg IV twice daily until symptoms resolve followed by a 2-week taper.²⁰¹ In severe cases, ATRA should be discontinued or another chemotherapeutic, typically cytarabine, should be added to ATRA in patients with high white blood cell counts.¹⁸⁴ ATRA

can be reintroduced upon resolution of DS.

VITAMIN D

History and Epidemiology

Rickets, a disease of urban children living in temperate zones, was thought to result from the lack of a dietary factor or adequate sunshine. In 1919, two independent groups demonstrated that rickets could be prevented or cured by either the addition of cod liver oil to the diet or exposure to sunlight.^{112,160} Vitamin D is found in cod liver oil and other foods, including butter, cheese, and cream, which contain 12 to 40 IU/100 g (0.3–1 µg/100 g), eggs, which contain 25 IU/100 g (0.6 µg/100 g), and fatty fish, such as salmon and mackerel, which contain 150 to 550 IU/100 g (4–14 µg/100 g) and 1100 IU/100 g (28 µg/100 g), respectively. Some foods typically are fortified with vitamin D, including cereals, bread, and milk.¹⁰⁵ Many dietary supplements, such as multivitamins, contain vitamin D.

Rickets has been eliminated as a major public health concern in children in Europe and North America since the fortification of milk with vitamin D. Outbreaks of vitamin D poisoning subsequently occurred in Europe in the 1950s because of excessive fortification of milk and cereals to compensate for wartime nutritional deprivation of children.⁵⁶ This vitamin D poisoning led to a period of prohibition of vitamin D fortification of foods.¹⁰⁵ More recently, a study showed that milk and infant formulas rarely contain the amount of vitamin D stated on the label and may be either significantly underfortified or overfortified, leading to vitamin D deficiency or toxicity.¹⁰⁵ One case series demonstrated vitamin D toxicity in eight patients who drank local dairy milk that was excessively fortified with vitamin D₃.¹¹⁷ Many cases of vitamin D toxicity result from continued supplementation of vitamin D and calcium initially prescribed for treatment of hypoparathyroidism, osteoporosis, or osteomalacia but inappropriately continued due among other reasons to inadequate patient physician communication.^{53,137,185} Two reports describe vitamin D toxicity in families secondary to use of a highly concentrated vitamin D preparation in nut oil that was not intended for human consumption.^{59,186} Another case report describes vitamin D poisoning secondary to contamination of table sugar with crystalline vitamin D₃.²³² Vitamin D toxicity has been reported in dogs secondary to vitamin D₃ exposure in the form of rodenticides.⁸¹ Vitamin D deficiency should not occur in individuals who eat a well-balanced diet and are exposed to adequate sunlight. Casual exposure of cutaneous tissues to ultraviolet light during the summer months should produce adequate vitamin D storage for winter months.⁹³ Total body sun exposure provides the vitamin D equivalent of 10,000 IU/day (250 µg/day); the body requires only a total vitamin D supply of 4000 IU/day (100 µg/day).²³⁰ Breast-fed infants may require supplemental vitamin D if they have limited exposure to sunlight because the vitamin D content of human milk is extremely low.⁴⁹ Other groups susceptible to vitamin D deficiency include the elderly, vegans, persons with darkly pigmented skin, and persons without adequate sunlight exposure such as those living in institutions.

The Institute of Medicine (IOM) recently found that although average total vitamin D intake was below the median requirement in North Americans, average serum concentrations of vitamin D were above the 20 ng/mL concentration that the IOM determined to be needed for good bone health. They suggested that sun exposure contributes meaningful amounts of vitamin D and that the majority of the population is meeting its needs for vitamin D.²⁰² Despite this finding, in 2010 the IOM revised its dietary reference intakes with an increase in the RDA for vitamin D across all age groups (Table 47–1).

The new RDA assumes minimal sunlight exposure and is 600 IU/day (15 µg/day) for nonelderly adults. The new RDA may lead to an increased number of persons taking vitamin D either by prescription or in the form of a dietary supplement. In addition, the IOM found that testing for vitamin D deficiency has become widespread.²⁰² However, the measurements or cut-points of sufficiency or deficiency used by laboratories are not based on scientific studies and there is no central regulatory authority determining which cut-point should be used. The IOM found that many laboratories use an inappropriately high cut-point for deficiency, thereby leading to an increased number of diagnoses of vitamin D deficiency and possibly persons taking unnecessary vitamin D supplements.

The use of vitamin D supplements to prevent and treat a variety of illnesses has increased substantially over the past decade.⁹⁵ Vitamin D deficiency is linked to autoimmune disease, cancer, cardiovascular disease, depression, dementia, infectious disease, musculoskeletal decline, and more.⁹⁵ However, the IOM concluded that vitamin D supplementation for indications other than musculoskeletal health is not supported by adequate scientific evidence.²⁰² Vitamin D is used for the prophylaxis and treatment of rickets, osteomalacia, and osteoporosis. It is also used for the treatment of hypoparathyroidism and skin conditions, including psoriasis.

Vitamin D is the name given to both ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃). In humans, both forms of vitamin D have the same biologic potency. One microgram of vitamin D is equivalent to 40 IU of vitamin D.

Pharmacology, Pharmacokinetics, and Toxicokinetics

Vitamin D itself is not biologically active and must go through extensive metabolism to an active form, whether it is ingested from a food source in the form of vitamin D₂ and D₃ or synthesized in the body. Vitamin D₃ is synthesized in the skin from 7-dehydrocholesterol (provitamin D₃) in a reaction catalyzed by ultraviolet B irradiation (Fig. 47–2).¹³⁷ Vitamin D₃ then is bound to vitamin D-binding protein, a protein that also binds vitamin D from the diet, and afterward enters the circulation. In the endoplasmic reticulum of the liver, vitamin D is metabolized to 25-hydroxyvitamin D {25(OH)D} by vitamin D-25-hydroxylase.⁸² Once formed, 25(OH)D is again bound to vitamin D-binding protein and transported to the proximal convoluted tubule in the kidney for hydroxylation to 1,25-dihydroxyvitamin D {1,25(OH)₂D}, or calcitriol, by 25(OH)D-1-α-hydroxylase.⁸² Once formed, 1,25(OH)₂D is secreted back into circulation, bound to vitamin D-binding protein, and delivered to target cells where it binds to receptors.

FIGURE 47–2. Schematic representation of the synthesis and physiologic response to vitamin D.

Vitamin D might be more appropriately called a hormone rather than a vitamin because it is synthesized in the body, circulates in the blood, and then binds to receptors in order to evoke its biologic action. The primary role of vitamin D is regulation of calcium homeostasis via interactions with the intestines and bones. Protein bound calcitriol is taken up by cells and then binds to a specific nuclear vitamin D receptor protein that, in turn, binds to regulatory sequences on chromosomal DNA.¹³⁷ The result is induction of gene transcription and translation of proteins that carry out the cellular functions of vitamin D. In the intestines, calcitriol increases the production of calcium binding proteins and plasma membrane calcium pump proteins, thereby increasing calcium absorption through the duodenum.¹²⁰ In the bone, calcitriol stimulates osteoclastic precursors to differentiate into mature osteoclasts.¹⁰⁶ Mature osteoclasts, together with PTH, lead to mobilization of calcium stores from bone, thereby raising serum concentrations of calcium. Given sufficient serum concentrations of calcium, calcitriol promotes bone mineralization by osteoblasts, resulting in increased deposition of

calcium hydroxyapatite into the bone matrix.¹⁰⁶ Calcitriol also binds to a vitamin D receptor in the parathyroid glands, which leads to decreased synthesis and secretion of PTH.¹⁷¹ The vitamin D receptor is present in most cells of the body including lymphocytes, epidermal skin cells, and tumor cells.²⁰⁵ The binding of calcitriol can inhibit proliferation and induce terminal differentiation.¹⁸⁸ Although the role of vitamin D has not been elucidated in all cells, abnormalities present during vitamin D deficiency may help identify the function of vitamin D in various tissues.

Vitamin D deficiency results in hypocalcemia, leading to increased secretion of PTH, which acts to restore plasma calcium concentrations at the expense of bone. In children, this situation leads to rickets in which newly formed bone is not adequately mineralized and results in bone deformities and growth defects. Adults develop osteomalacia, a disease characterized by undermineralized bone matrix. Patients typically present with bone pain and tenderness and proximal muscle weakness. Bone deformities are limited to the advanced stages of disease.

The literature varies regarding the toxic dose of vitamin D, with little scientific data available for corroboration. The current upper level intake is set at 4000 IU/day (100 µg/day) for persons aged 9 years and older, with lower levels set for children younger than 9 years of age.²⁰² This is an increase compared to the previous tolerable upper intake dose of 2000 IU/day (50 µg/day).²³⁰ There also are studies showing that doses as high as 4400 IU/day (110 µg/day) and 100,000 IU (2500 µg) for 4 days did not result in adverse effects.^{219,226,230} Case reports describe toxicity in the setting of vitamin D intake of 50,000 to 600,000 IU or, simply, doses in the milligram range, daily for prolonged periods.^{53,90,146,185}

Pathophysiology

The hallmark of vitamin D toxicity is hypercalcemia. Vitamin D in the form of 1,25(OH)₂D promotes calcium absorption from the gut and mobilization of calcium from bone. Vitamin D toxicity may be associated with a serum concentration of 25(OH)D 20 times higher than normal, whereas the concentration of 1,25(OH)₂D remains exceedingly variable.^{82,186} 25-Hydroxyvitamin D can mimic the action of 1,25(OH)₂D when it is present in excess and can bind to receptors usually specific for 1,25(OH)₂D.^{82,137} Alternatively, 25(OH)D, which has a higher affinity for vitamin D-binding protein compared to 1,25(OH)₂D, may preferentially bind to vitamin D-binding protein when it is present in elevated concentrations, displacing 1,25(OH)₂D and allowing it to circulate in an unbound form, or loosely bound to albumin.²³¹ A study of patients with vitamin D toxicity who had normal or near normal total 1,25(OH)₂D concentrations had elevated free 1,25(OH)₂D concentrations.¹⁸⁶ The availability of 1,25(OH)₂D to its receptors likely is increased, resulting in vitamin D toxicity.

Clinical Manifestations

Patients with vitamin D toxicity present with signs and symptoms characteristic of hypercalcemia.¹³⁷ Early manifestations include weakness, fatigue, somnolence, irritability, headache, dizziness, muscle and bone pain, nausea, vomiting, abdominal cramps, and diarrhea or constipation (Chap. 19). As the calcium concentration increases, hypercalcemia may induce polyuria and polydipsia. Diuresis results in salt and water depletion, further impairing calcium excretion. Severe hypercalcemia may present with ataxia, confusion, psychosis, seizures, coma, and acute kidney injury. In addition, cardiac dysrhythmias result from a shortened refractory period and slowed conduction. Findings on electrocardiography include increased PR intervals, widening of QRS complexes, QT shortening, and flattened T waves (Chap. 16).¹⁷³ Patients can develop metastatic calcification of the kidneys, blood vessels, myocardium, lung, and skin. Several patients with vitamin D toxicity have presented with anemia.^{191,207} Proposed mechanisms for anemia include a direct effect of vitamin D on hematopoietic cells and inhibition of erythropoietin production.¹⁹¹

Diagnostic Testing

Vitamin D toxicity should be considered in patients presenting with signs and symptoms of hypercalcemia. In addition to an elevated serum calcium concentration, laboratory results may reveal hyperphosphatemia given that vitamin D facilitates phosphate absorption in the small intestine, enhances its mobilization from bone, and decreases its excretion by the kidney.¹⁵¹ The diagnosis should be suspected in children with nephrocalcinosis and hypercalciuria even if serum calcium and phosphorus concentrations are normal.¹⁶⁶ Serum 25(OH)D can be measured, but it is unlikely that results will be available quickly. According to the IOM, the desired 25(OH)D concentration range is 20 to 50 ng/mL.²⁰² The IOM also found that concentrations higher than 30 ng/mL were not consistently associated with increased benefit and concentrations higher than 50 ng/mL may be cause for concern.

Management

Treatment of hypercalcemia in patients with vitamin D toxicity should include discontinuation of both vitamin D and calcium supplementation, maintenance of a low calcium diet, and administration of adequate volumes of oral or IV fluid to

increase renal calcium clearance.¹³⁷ Many cases of hypercalcemia will respond to such supportive care. Following rehydration, a loop diuretic, such as furosemide, can be added to promote calcium excretion.¹³⁷ Corticosteroids, such as hydrocortisone 100 mg/day or prednisone 20 mg/day, improve hypercalcemia and hypercalciuria in vitamin D poisoning. Studies have attempted to explain this effect as being a result of either decreased intestinal calcium absorption or inhibition of bone resorption.^{125,221} Bisphosphonates, such as pamidronate 90 mg IV and clodronate 600 mg IV, were used successfully in cases of severe hypercalcemia.^{136,196} These drugs inhibit bone resorption via actions on osteoclasts. Their use may preclude the need for hemodialysis in refractory cases of hypercalcemia. Calcitonin, a hypocalcemic hormone secreted by the thyroid gland that directly inhibits osteoclast activity, can be used to decrease bone resorption. Salmon calcitonin was successfully used to treat refractory hypercalcemia in a child with vitamin D poisoning. The dose utilized was 4 units/kg IM twice daily until hypercalcemia resolved at 15 days.¹⁶¹ Of note, studies have led the FDA to conclude that salmon calcitonin in the form of a nasal spray for the treatment of postmenopausal osteoporosis is associated with an increased risk of cancer.³⁷

ANTIOXIDANTS (VITAMINS E AND C)

The antioxidants include vitamins E and C and β -carotene. During the 1990s, the concept that antioxidants had a protective effect against atherosclerosis and carcinogenesis was widely promoted. This notion was based on the “oxidative-modification hypothesis” of atherosclerosis, which proposes that atherogenesis is initiated by lipid peroxidation of LDL.⁵⁷ Unregulated or prolonged production of cellular oxidants leading to oxidant induced DNA damage is thought to be responsible for carcinogenesis.¹²⁸ Epidemiologic evidence seems to support the use of antioxidants for these indications.^{130,194,218} However, several prospective, randomized, placebo controlled clinical trials, designed to test for the effect of antioxidant vitamins on cardiovascular disease and cancer, have consistently shown that commonly used antioxidant regimens do not significantly reduce or prevent overall cardiovascular events or cancer.^{34,98,102,174,224,245}

VITAMIN E

History and Epidemiology

The existence of vitamin E was first demonstrated in 1922 by researchers noting that female rats deficient in a dietary principle were unable to sustain a pregnancy.⁶⁶ Testicular lesions in male rats were described in deficiency states and vitamin E was referred to as the “anti-sterility vitamin.”¹⁵³ Vitamin E was first isolated from wheat-germ oil in 1936.⁶⁵ The richest sources of vitamin E include nuts, wheat germ, whole grains, vegetable and seed oils, including soybean, corn, cottonseed, and safflower, and the products made from these oils. In general, animal products are poor sources of vitamin E. Human milk, by contrast to cow’s milk, has sufficient vitamin E in the form of α -tocopherol to meet the needs of breast fed infants.¹⁵³ Supplementation should not be necessary in persons who consume a well-balanced diet.

Vitamin E deficiency occurs in patients with malabsorption syndromes, which may occur in the presence of pancreatic insufficiency or hepatobiliary disease, such as biliary atresia.²⁷ Patients with abetalipoproteinemia are at risk for vitamin E deficiency.¹⁴ In this rare disease, absorption and transport of vitamin E are impaired secondary to a lack of chylomicron and β -lipoprotein formation. Manifestations of deficiency are variable, but seem to have the most effect in organ systems that rely on vitamin E for normal functioning.¹⁵³ The clinical syndrome is primarily manifested by a peripheral neuropathy and spinocerebellar syndrome that improves with supplemental vitamin E.¹⁶² Symptoms include ophthalmoplegia, hyporeflexia, gait disturbances, and decreased sensitivity to vibration and proprioception.²⁷

Vitamin E is an essential nutrient. It is believed to be necessary for normal functioning of the nervous, reproductive, muscular, cardiovascular, and hematopoietic systems. Use of vitamin E has been proposed for a wide range of conditions. In most cases, scientific rationale for its use is lacking or is based on in vitro or animal data that have not been validated in

humans or have demonstrated equivocal results.²⁷ As examples, vitamin E has been used for treatment of recurrent abortion, hemolytic anemias, claudication, wound healing, tardive dyskinesia, epilepsy, and adult respiratory distress syndrome. In addition, much research over the past decade has focused on the use of vitamin E for the prevention and treatment of cardiovascular disease and cancer, with disappointing results.²²⁵

Vitamin E includes eight naturally occurring compounds in two classes—tocopherols and tocotrienols—that have differing biologic activities. The most biologically active form is RRR- α -tocopherol, previously known as d- α -tocopherol, which is the most widely available form of vitamin E in food. A synthetic form of α -tocopherol, often used in vitamin supplements, contains a mixture of d and l isomers and is designated all-rac- α -tocopherol (previously d,l- α -tocopherol). One IU is equivalent to 1 mg α -tocopherol acetate (ALPHA-TA).

Pharmacology, Pharmacokinetics, and Toxicokinetics

Vitamin E absorption is dependent on the ingestion and absorption of fat. The presence of bile also is essential. Vitamin E is passively absorbed in the intestinal tract into the lymphatic circulation by a nonsaturable process. Approximately 45% of a dose is absorbed in this manner and subsequently enters the bloodstream in chylomicrons, which are taken up by the liver. Vitamin E then is secreted back into the circulation, where it is primarily associated with LDL. Vitamin E is distributed to all tissues, with the greatest accumulation in adipose tissue, liver, and muscle.

The primary biologic function of vitamin E is as an antioxidant. It prevents damage to biologic membranes by protecting polyunsaturated fats within membrane phospholipids from oxidation.³⁵ It accomplishes this task by preferentially binding to peroxy radicals and forming the corresponding organic hydroperoxide and tocopheroxyl radical, which, in turn interacts with other antioxidant compounds, such as ascorbic acid, thereby regenerating tocopherol. Vitamin E may be responsible for cell growth and proliferation by combating the inhibitory effects of lipid peroxidation.¹⁶² Vitamin E may have a negative role in the regulation of cellular proliferation through its nonoxidant properties, such as inhibition of protein kinase C activity.¹⁶²

Large amounts of vitamin E, ranging from 400 to 800 IU/day (400–800 mg/day) for months to years, were previously thought to be without apparent harm.⁴⁹ Vitamin E supplementation results in few obvious adverse effects, even at doses as high as 3200 mg/day (3200 IU/day).²⁰ In several species, the oral median lethal dose was 2000 mg/kg (2000 IU/kg) or more, and significant adverse effects were observed only when daily doses were greater than 1000 mg/kg (1000 IU/kg), equivalent to 200 to 500 mg/kg (200–500 IU/kg) in humans.¹⁶³ However, a meta-analysis reveals that all cause mortality may increase at doses equal to or greater than 400 IU/day (400 mg/day).¹⁶⁴

Pathophysiology

In vitro studies demonstrate that in high doses vitamin E may have a paradoxical prooxidant effect.^{2,33,164} The prooxidant effect of vitamin E on LDLs is related to the production of α -tocopheroxyl radicals, which normally are inhibited by other antioxidants such as vitamin C. High doses of vitamin E may displace other antioxidants, thereby disrupting the natural balance of the antioxidant system and increasing vulnerability to oxidative damage.¹¹¹ High doses of vitamin E may inhibit human cytosolic glutathione S-transferases, enzymes that are active in the detoxification of xenobiotics and endogenous toxins.²²⁹

Clinical Manifestations

Gastrointestinal symptoms, including nausea and gastric distress, were reported in patients who had received vitamin E 2000 to 2500 IU/day (2000–2500 mg/day).^{103,239} Diarrhea and abdominal cramps were reported in patients who received a dose of 3200 IU/day (3200 mg/day).⁸ Reports of other adverse effects, including fatigue, weakness, emotional changes, thrombophlebitis, increased serum creatinine concentration, and decreased thyroid hormone concentrations, have not been reproduced in other case series or clinical trials.¹⁶³

The most significant toxic effect of vitamin E, at doses exceeding 1000 IU/day (1000 mg/day), is its ability to antagonize the effects of vitamin K.⁴⁹ Vitamin E appears to increase the epoxidation of vitamin K to its inactive form, thereby increasing the vitamin K requirement several fold.^{21,233} Although high oral doses of vitamin E typically do not produce a coagulopathy in normal humans with adequate vitamin K stores, coagulopathy may develop in vitamin K deficient patients or those taking warfarin.^{21,47,69,233} Animal studies demonstrate that absorption of both vitamins A and K is impaired by large doses of vitamin E.^{27,197}

Use of an IV vitamin E preparation (E-Ferol) was associated with a severe epidemic of unexplained thrombocytopenia, kidney dysfunction, hepatomegaly, cholestasis, ascites, hypotension, and metabolic acidosis in low birth weight infants in several neonatal intensive care units in the early 1980s.³² Use of polysorbate 20 and polysorbate 80 for emulsification of lipids and fat-soluble vitamins in this IV vitamin E product was implicated as the cause of this syndrome, rather than vitamin E.

VITAMIN C

MW = 176.12 Da
Therapeutic serum concentration = 0.4–2.0 mg/dL

History and Epidemiology

Vitamin C, also known as ascorbic acid, has long been used as a preventative for the common cold. Interestingly, an extensive review of 14 studies of the role of vitamin C in the treatment of the common cold suggested that only eight were valid investigations, and none of the studies demonstrated any therapeutic benefit.⁴¹ Its function as an antioxidant has led to its use for the prevention and treatment of cardiovascular disease and cancer. Human data from clinical trials have failed to demonstrate that vitamin C significantly reduces or prevents overall cardiovascular events or cancer. Vitamin C may have a role as a reducing agent in the treatment of idiopathic methemoglobinemia ([Chap. 127](#)). However, it is less effective than standard treatment with methylene blue; therefore, it is not routinely indicated.¹⁵² Vitamin C is popularly used to promote wound healing, treat cataracts, combat chronic degenerative diseases, counteract the effects of aging, increase mental attentiveness, and decrease stress.^{47,163} However, little, if any, objective data demonstrate a benefit of treatment for any of these indications.⁴⁹

Vitamin C has long been associated with prevention of scurvy.¹⁵² In 1747, James Lind, a physician in the British Royal Navy, analyzed the relationship between diet and scurvy and confirmed the protective and curative effects of citrus fruits. Vitamin C was isolated from cabbage in 1928 and subsequently shown in 1932 to be the active antiscorbutic factor in lemon juice. It was given the name ascorbic acid to indicate its role in preventing scurvy. Other dietary sources of vitamin C include tomatoes, strawberries, and potatoes. Today, those at risk for developing scurvy include the elderly, alcoholics, chronic drug users, and others with inadequate diets, including infants fed formula diets with insufficient concentrations of vitamin C.¹⁵² Symptoms include gingivitis, poor wound healing, bleeding, and petechiae and ecchymoses. Musculoskeletal signs and symptoms consisting of arthralgias, myalgias, hemarthrosis, and muscular hematomas develop in 80% of cases.⁶⁷ Children experience severe pain in their lower limbs secondary to subperiosteal bleeding.⁶⁷

Pharmacology, Pharmacokinetics, and Toxicokinetics

Following ingestion, intestinal absorption of vitamin C occurs via an active transport system that is saturable.¹⁹⁵ The absorptive capacity is reached with ingestion of approximately 3 g/day, and vitamin C dietary supplements are commonly taken in doses of 500 mg/day. When given as a single oral dose, absorption decreases from 75% at 1 g to 20% at 5 g. Vitamin C is distributed from the plasma to all cells in the body. Tissue uptake is also a saturable process.¹⁶³ Metabolic degradation of vitamin C to oxalate accounts for 30% to 40% of oxalate excreted daily.⁹⁴ Because absorption and metabolic conversion are saturable, large ingestions of vitamin C should not significantly increase oxalate production.²¹¹ Only a small amount of vitamin C is filtered through the glomeruli, and tubular resorption, a saturable process that may compete with uric acid, usually is almost complete.²⁴ Plasma concentrations of vitamin C typically are maintained at approximately 1 mg/dL. The kidney efficiently eliminates excess vitamin C as unchanged ascorbic acid.

Vitamin C is a cofactor in several hydroxylation and amidation reactions by functioning as a reducing agent.^{139,140} As a result, vitamin C plays an important role in the synthesis of collagen, carnitine, folinic acid, and norepinephrine. It also influences the processing of hormones such as oxytocin, antidiuretic hormone, and cholecystokinin. Vitamin C reduces iron from the ferric to the ferrous state in the stomach, thereby increasing intestinal absorption of iron. Vitamin C may be involved in steroidogenesis in the adrenals. Vitamin C also has a prooxidant effect in vivo.¹⁸⁷ This effect is not believed to occur at doses less than 500 mg/day but may occur in the setting of overdose.

Clinical Manifestations

The possibility of oxalate nephrolithiasis should not be a significant clinical concern.⁸⁴ Nevertheless, conflicting studies and reports exist regarding the association between vitamin C overdose and the development of oxalosis. A prospective study on the risk of kidney stones in men did not support an association between high daily vitamin C intake and stone

formation.⁵⁰ This was also demonstrated in a study involving daily ingestion of 4 g of ascorbic acid for five days in healthy men in which there was no increase in urinary oxalate excretion.¹² Another study did show increased rates of oxalate absorption and endogenous synthesis contributing to hyperoxaluria, but this effect was found in individuals with a prior history of renal calcium oxalate stones and not in individuals without a prior history of calcium oxalate stones.⁴⁰ Some reports of high urine oxalate concentrations likely were erroneous because of conversion of ascorbate to oxalate in alkaline urine samples left standing after collection.^{12,236} By contrast, other reports show an increase in urinary oxalate and calcium oxalate crystallization following ingestion of high doses of vitamin C in both stone-formers and non-stone-formers.^{18,155} Individual case reports documenting the presence of oxalate stones in the setting of vitamin C overdose often have involved IV administration.^{48,83,134,156,222,244} Oxalosis is also more likely to develop in patients with chronic kidney disease.^{16,163} Gastrointestinal effects of high doses of vitamin C may include localized esophagitis, given prolonged mucosal contact with ascorbic acid, and an osmotic diarrhea.^{108,235}

VITAMIN B₆

History

Pyridoxine, pyridoxal, and pyridoxamine are related compounds that have the same physiologic properties. Although all three compounds are included in the term vitamin B₆, the vitamin has been assigned the name pyridoxine. This vitamin was discovered in 1936 as the water-soluble factor whose deficiency was responsible for the development of dermatitis in rats.¹⁵² In humans, deficiency is characterized by cheilosis, stomatitis, glossitis, blepharitis, and a seborrheic dermatitis around the eyes, nose, and mouth.²⁰³ More importantly, pyridoxine deficiency is associated with seizures.

Pyridoxine is found in several foods, including meat, liver, whole-grain breads and cereals, soybeans, and vegetables.¹⁵² Deficiency should not occur in humans who eat a well balanced diet.²¹⁵

Pyridoxine is popularly used as a component of bodybuilding regimens and for treatment of premenstrual syndrome and carpal tunnel syndrome.^{1,62} High doses have been used for treatment of schizophrenia and autism with variable results.^{74,138}

Pharmacology

All forms of vitamin B₆ are well absorbed from the intestinal tract. Pyridoxine is rapidly metabolized to pyridoxal, pyridoxal phosphate (PLP), and 4-pyridoxic acid.²⁴⁶ PLP accounts for approximately 60% of circulating vitamin B₆ and is the primary form that crosses cell membranes.¹⁵² Most vitamin B₆ is renally excreted as 4-pyridoxic acid, with only 7% excreted unchanged in the urine.^{152,246} Experiments in anephric rats demonstrate an up to ten fold increase in susceptibility to pyridoxine induced neurotoxicity, suggesting a need for caution when prescribing pyridoxine to patients with chronic kidney disease.¹⁴¹

Pyridoxal phosphate is the active form of vitamin B₆. It is a coenzyme required for the synthesis of γ -aminobutyric acid (GABA), an inhibitory neurotransmitter. Decreased GABA formation in the setting of pyridoxine deficiency may contribute to seizures.¹⁵² Isoniazid and other hydrazines inhibit the enzyme responsible for conversion of pyridoxine to PLP (Chap. 58).¹⁰⁷ Therefore, pyridoxine should be administered concomitantly with isoniazid to limit the development of a peripheral neuropathy. Seizures resulting from isoniazid overdose often are successfully treated with pyridoxine (Antidotes in Depth: A14).

Pathophysiology

Interestingly, similar to pyridoxine deficiency, pyridoxine toxicity is characterized by neurologic effects. The pathophysiology of pyridoxine neurotoxicity is not well defined. However, studies indicate that the mammalian peripheral sensory nervous system is vulnerable to large doses of pyridoxine.²⁰⁸ Peripheral sensory nerves may be particularly

vulnerable to circulating xenobiotics because of the permeability of their associated blood vessels.²⁰⁸ Compared with the CNS, these nerves lack the blood brain barrier. In addition, the nerves of the CNS may be relatively shielded from pyridoxine toxicity because pyridoxine is transported into the CNS by a saturable mechanism.²⁰⁸ In 1942, pyridoxine was recognized to cause severe weakness and pathological changes in peripheral nerves and dorsal root ganglia in dogs and rats.^{9,217} Administration of IV pyridoxine 2 g/kg in two patients for the treatment of mushroom poisoning resulted in permanent dorsal root and sensory ganglia deficits.⁴

Clinical Manifestations

Chronic overdoses are associated with progressive sensory ataxia and severe distal impairment of proprioception and vibratory sensation. Touch, pain, and temperature sensation may be minimally impaired, and reflexes may be diminished or absent. These findings were first described in 1983 in a case series of seven patients who were taking pyridoxine 2–6 g/day for 2 to 40 months for premenstrual syndrome.²⁰⁸ Nerve conduction and somatosensory studies in these patients showed dysfunction in the distal sensory peripheral nerves. Nerve biopsy showed widespread, nonspecific axonal degeneration. This syndrome has since been reported with pyridoxine doses as low as 200 mg/day.¹⁸³ Among 26 patients with elevated serum pyridoxine concentrations, the most common symptoms reported were numbness (96%), burning pain (49.9%), tingling (57.7%), balance difficulties (30.7%), and weakness (7.8%).²¹⁰ In most cases, symptoms gradually improved over several months with abstinence from pyridoxine. However, symptoms may still progress for 2 to 3 weeks after pyridoxine discontinuation.²³

Acute neurotoxicity may occur when a massive amount of pyridoxine is administered as a single dose or given over a few days.⁴ Large overdoses of pyridoxine are associated with incoordination, ataxia, seizures, and death.²²⁷

NICOTINIC ACID

History

Nicotinic acid, or niacin, was discovered to be an essential dietary component in the early 1900s.⁸⁷ A deficiency of this vitamin, also known as vitamin B₃, causes pellagra, which is characterized by dermatitis, diarrhea, and dementia. This disease had been prevalent for centuries in countries that heavily relied on maize as a dietary staple until it was determined that pellagra could be prevented by increasing dietary intake of fresh eggs, milk, and fresh meat, including liver.¹⁵² Other food sources of nicotinic acid include fish, poultry, nuts, legumes, and whole-grain and enriched breads and cereals. Supplementation of flour with nicotinic acid in 1939 probably is responsible for the near eradication of this disease in the United States. Chronic alcohol users still develop pellagra, likely secondary to malnutrition.

Niacin was introduced as a treatment for hyperlipidemia in 1955.⁷ Nicotinic acid reduces triglyceride synthesis, with a resultant drop in very-low-density lipoprotein cholesterol and LDL cholesterol and a rise in high-density-lipoprotein cholesterol.⁸⁷ Therapy usually is started with single doses of 100 to 250 mg. Frequency of dose and total daily dose are gradually increased until a dose of 1.5 to 2.0 g/day is reached. If the LDL cholesterol concentration is not sufficiently decreased with this dosing regimen, then the dose is further increased to 3.0 g/day. These doses of niacin are 100-fold higher than the amount necessary to meet adult nutritional needs.¹⁹²

More recently, the nonmedicinal ingestion of niacin for the purpose of altering or masking the results of urine testing for illicit drugs was noted.^{11,39,167} However, there is no evidence that ingestion of niacin is capable of this effect.

Pharmacology, Pharmacokinetics, and Toxicokinetics

Nicotinic acid is well absorbed from the intestinal tract and is distributed to all tissues. With therapeutic dosing, little unchanged vitamin is excreted in the urine. When extremely high doses are ingested, the unchanged vitamin is the major urinary component. Nicotinic acid ultimately is converted to nicotinamide adenine dinucleotide (NAD⁺) and nicotinamide adenine dinucleotide phosphate (NADP⁺), which are the physiologically active forms of this vitamin. NADH and NADPH, the reduced forms of NAD⁺ and NADP⁺ respectively, act as coenzymes for proteins that catalyze oxidation–reduction

reactions that are essential for tissue respiration.¹⁵²

Clinical Manifestations

The most common adverse effect associated with niacin use is a vasodilatory cutaneous flushing described as a sense of warmth in the face, ears, neck, trunk, and less frequently in the extremities, lasting less than 1 to 2.5 hours.¹¹⁶ Other symptoms include erythema, itching, and tingling. These effects may occur at doses of 0.5 to 1.0 g/day.¹⁵⁸ Symptoms commence within 15 to 30 minutes after ingestion of immediate-release niacin, 30 to 120 minutes after ingestion of extended-release niacin, and at more variable times after ingestion of sustained-release niacin.¹¹⁶ Symptoms are caused by the production of prostaglandin (PG) D₂ and E₂ via the G protein-coupled receptor, GPR109A.²² Flushing occurs because of the predilection of the skin as a site of prostaglandin production after niacin ingestion.²²⁰ PGD₂ and PGE₂ act on receptors DP₁ and EP_{2/4} in dermal capillaries causing vasodilation.¹²² Vasodilatory adverse events occur in almost all of patients, particularly when given an immediate release form of niacin.¹⁵⁸ Many patients discontinue niacin use because of flushing. Long-term tolerance to flushing does develop with continued dosing of niacin, secondary to decreased PGD₂ output.¹¹⁶

Because rapid absorption of niacin seems to be related to development of flushing, modified release preparations of niacin were developed. A meta-analysis of 4000 patients who had used various time-release preparations of niacin showed that among the 70% of patients who experienced flushing, 85% had used immediate release niacin, 66% used extended release niacin, and 26% had used sustained-release niacin.³¹ The modified release preparations are more likely to produce gastrointestinal adverse events, such as epigastric distress, nausea, and diarrhea.¹⁵⁸ In addition, niacin-induced hepatotoxicity occurs more frequently and is more severe in patients treated with modified release niacin rather than immediate-release niacin.^{44,192} Elevated hepatic aminotransferases may occur with doses as low as 1 g/day, whereas symptoms of hepatic dysfunction occur at doses of 2 to 3 g/day.¹⁵⁸ These patients may have elevated serum bilirubin and ammonia concentrations and a prolonged prothrombin time. They may present with fatigue, anorexia, nausea, vomiting, and jaundice. In most cases, liver function improves following niacin withdrawal.^{64,158} Severe cases have progressed to fulminant hepatic failure and hepatic encephalopathy.^{45,104,169}

Niacin also causes amblyopia, hyperglycemia, hyperuricemia, coagulopathy, myopathy, and hyperpigmentation.¹⁰¹ A recent case of a 16 year-old boy who ingested 13 g of niacin over 48 hours described the development of metabolic acidosis, hypoglycemia, elevated hepatic aminotransferases, and coagulopathy.¹¹ The patient also complained of severe myalgias and chest and abdominal pain. His signs and symptoms resolved after 5 days with intravenous fluid resuscitation and bicarbonate infusion.

Management

A dose of 325 mg of aspirin taken 30 minutes before ingestion of niacin diminishes flushing.²⁴¹ This is because aspirin inhibits cyclooxygenase, thereby decreasing production of prostaglandins.

Other strategies for reducing flushing include dosing with meals, and avoidance of alcohol, hot beverages, spicy foods, and hot baths or showers close to or after dosing.⁵² Flushing may also be decreased by starting at a low dose and gradually increasing to the full dose. Tolerance to flushing may develop after several weeks, but flushing will recur if doses are missed.

Laropiprant, a PGD₂ antagonist at receptor DP₁, has demonstrated efficacy in numerous studies (phase 1, 2, and 3 trials) for reducing niacin-associated flushing.¹¹⁶ In Europe, laropiprant was approved for use in 2008 in the form of a combined tablet, 1000 mg of extended release niacin with 20 mg laropiprant, and sold under the trade name Tredaptive (Merck & Co; known outside the United States as MSD). Also in 2008, the FDA did not give approval for a similar product with the trade name Cordaptive made by the same pharmaceutical company. In 2013, the HPS2-THRIVE (Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events) collaborative group reported an increased incidence of myopathy among patients taking simvastatin plus extended release niacin/laropiprant (ERN/LRPT) compared to those taking simvastatin plus placebo.¹⁰⁹ Also, ERN/LRPT in addition to statin therapy did not significantly reduce the risk of major vascular events in patients with well controlled LDL-cholesterol concentrations. As a result, the study was halted and Merck & Co plans to cease production of Tredaptive. Other findings included that 25.4% of participants taking ERN/LRPT stopped their randomized treatment compared with 16.6% taking placebo, mostly due to adverse dermatologic and gastrointestinal effects.

Recent in vitro studies demonstrate that methylnicotinate induces serotonin release from human platelets in addition to PGD₂ release from human mast cells.¹⁷⁹ Animal studies demonstrate the ability of various serotonin antagonists including cyproheptadine to inhibit the niacin-induced temperature increase, associated with flush, by 90%.¹⁷⁹ Flavanoids have been studied as a potential treatment for niacin flush due to their ability to inhibit both niacin-induced plasma PGD₂ and

serotonin increase in a rat model.¹⁸⁰ In a small human study, a dietary supplement containing 150 mg of the flavanoid quercetin decreased the severity and longevity of erythema and burning sensation scores on a visual scale.¹²¹

SUMMARY

- Healthy adults consuming a well-balanced diet do not require vitamin supplementation.
- Vitamins are popularly believed to be a panacea and are commonly taken in supraphysiologic doses.
- Because the therapeutic index is large, toxicity generally does not develop unless very large doses are taken for sustained periods.
- Health care professionals should consider hypervitaminosis in the differential diagnosis when patients present with symptoms consistent with a vitamin toxicity syndrome.
- A thorough history, with emphasis on diet and prescribed and supplemental vitamin use, is important.

C. PHARMACEUTICALS

CASE STUDY 3

History A 27 year-old man was found acting abnormally in a train station. When approached by police, he seemed to be hallucinating and answered questions inappropriately, so emergency medical services was activated. When the paramedics arrived, they recorded a blood pressure of 148/92 mm Hg, a pulse of 142 beats/min, and a respiratory rate of 16 breaths/min. They noted dilated pupils and disorientation, but did not comment on other abnormalities. An intravenous line was inserted, and the patient was given oxygen via nasal canula at 4 L/min during transport to the hospital. No further history could be obtained because the patient could not be understood.

Physical Examination On arrival to the hospital, the patient appeared to be a well nourished, appropriately dressed man in significant distress. Vital signs were: blood pressure, 152/92 mm Hg; pulse, 155 beats/min; respiratory rate, 22 breaths/min; rectal temperature, 99.4°F; oxygen saturation, 100% on nasal canula at 4 L/min; and glucose, 117 mg/dL. Physical examination revealed a normal head without signs of trauma, the pupils were 7 to 8 mm and not reactive (**Fig. CS3–1**), and the extraocular muscles appeared normal. His neck was supple. His chest was clear to auscultation, and other than tachycardia, his heart sounds were normal. His abdomen was slightly distended and tender in the suprapubic area with absent bowel sounds. His skin was warm and dry. The neurologic examination was notable for good strength in all four extremities with intermittent myoclonic jerking, slight symmetrical hyperreflexia, and plantar flexion. He was mumbling incoherently looking about the room as if he were responding to external stimuli and could not answer questions.

FIGURE CS3–1. The patient's right eye demonstrating a large and fixed pupil.

Because the patient could not provide any history, his belongings were searched for possible information. Despite being well dressed, he had no wallet, cell phone, pills, or other useful information in his pockets.

What Is the Differential Diagnosis? The patient's presentation is notable for hypertension, tachycardia, and tachypnea with dilated pupils and hallucinations. The toxicologic differential diagnosis of these findings includes anticholinergics and antihistamines (**Chap. 49**), certain antipsychotics and antidepressants (**Chaps. 70** and **71**), alcohol and sedative–hypnotic withdrawal (**Chap. 81**), sympathomimetics such as cocaine and amphetamines (**Chaps. 76** and **78**), and hallucinogens (**Chap. 82**). However, a more detailed evaluation of the physical examination is suggestive of an anticholinergic toxic syndrome (**Chap. 3**) in that the skin is dry, the pupils are poorly responsive, and the bowel sounds are diminished. All of these findings are inconsistent with sympathomimetics, hallucinogens, and alcohol or sedative–hypnotic withdrawal. Although cyclic antidepressants and some antipsychotics are potent anticholinergics, their toxicity is usually associated with hypotension and somnolence.

Immediate Assessment and Management In the setting of suspected anticholinergic toxicity, the single most important diagnostic test is to obtain an electrocardiogram (ECG). The ECG is used primarily to identify signs of sodium channel

blockade that are characteristic of cyclic antidepressant overdose (Chaps. 16 and 71) but also occur with some phenothiazine antipsychotics (Chap. 70), diphenhydramine (Chap. 49), type IA and IC antidysrhythmics (Chap. 64), cocaine (Chap. 78), and some other xenobiotics. A prolonged QRS complex duration would not only help provide a diagnosis but would also indicate the need to intervene with hypertonic sodium bicarbonate (Antidotes in Depth: A5). The patient's ECG is shown in Fig. CS3–2.

FIGURE CS3–2. ECG showing sinus tachycardia with a QRS duration of 90 msec, a QT interval of 320 msec (QTc 506 msec) and findings consistent with early sodium channel blockade (an S wave in I and an R wave in aVR despite a relatively normal QRS complex duration).

Additional life-threatening conditions that might be associated with anticholinergic toxicity include hyperthermia, seizures, and rhabdomyolysis. These problems should be anticipated. Laboratory analysis was sent for a complete blood count, electrolytes, creatine phosphokinase, and concentrations of acetaminophen and ethanol.

Further Diagnosis and Treatment The combination of a clinical anticholinergic toxic syndrome with subtle markers of sodium channel blockade was most suggestive of diphenhydramine toxicity. Given that the patient was uncomfortable and unable to provide a history, a decision was made to administer physostigmine (Antidotes in Depth: A9). Atropine was brought to the bedside, and the patient was attached to a cardiac monitor. One milligram of physostigmine was infused over 5 minutes. Over the next few minutes, the patient's pupils appeared smaller, and his heart rate dropped to 110 beats/min. He became calm, but his speech was still garbled and incoherent, and his bowel sounds were quiet. A second dose of 1 mg of physostigmine was given over 5 minutes. Shortly thereafter, the patient's voice became clear, and he asked to drink water and use a urinal. He spontaneously voided 800 mL of clear urine. His blood pressure was 132/84 mm Hg, and his pulse was 98 beats/min.

He related that he had no past medical history, no past surgical history, and no allergies to medications and was not taking any prescription, nonprescription, or illicit drugs. The last thing he remembered was that he was early for his train and went to the station bar for a drink with someone he met while waiting.

Case Resolution All of the patient's laboratory tests were within normal limits except for his blood ethanol concentration, which was 32 mg/dL. The health care team was concerned about drug facilitated robbery and had the department social worker meet with the patient. He was offered the opportunity for comprehensive testing as well as filing a report with the police, which he declined. He was observed for 8 hours and remained well, so he was discharged at his own request.

48 ANTIEPILEPTICS

Suzanne Doyon

HISTORY AND EPIDEMIOLOGY

Historically, seizures were treated by a variety of methods, including ketogenic diets, fluid restriction, and surgical excision of scars or irritable cortical foci. The first truly effective antiepileptic therapy was introduced in 1857, when the administration of bromides was noted to sedate patients and significantly reduce their seizures. Phenobarbital, a sedative–hypnotic, was first used to treat seizures in 1912. Most of the subsequently introduced antiepileptics such as primidone had chemical structures similar to that of phenobarbital, and sedation was erroneously believed to be an essential component of antiepileptic therapy.

The search for nonsedating antiepileptics led to the introduction of phenytoin in 1938.¹¹⁶ After 1965, benzodiazepines, carbamazepine, and valproic acid (VPA) were introduced and gained wide use as antiepileptics. These antiepileptics were the only new medications available until the 1990s when gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, felbamate, vigabatrin, lacosamide, and zonisamide were introduced.

Antiepileptics are also currently used for treating mood disorders, refractory pain syndromes such as trigeminal neuralgia, bruxism, migraine headaches, drug withdrawal syndromes, and social phobias. A warning, based on a meta-analysis of placebo-controlled trials, placed the risk of suicide twice as high among patients receiving antiepileptics as compared with those receiving placebo.^{30,78} More specifically, other authors reported an association between mood disorders treated with antiepileptics and suicides.¹³³ Conversely, others observed that rates of depression are high among patients with epilepsy, whether well controlled with antiepileptics or not.⁷

This chapter reviews the toxicity and management of overdoses with antiepileptics other than the benzodiazepines and barbiturates, which are discussed in [Chap. 74](#).

PHARMACOLOGY

The mechanisms of action of antiepileptics are fourfold: sodium or calcium channel inhibition, inhibition of excitatory amines, GABA (γ -aminobutyric acid) related, and binding to synaptic vesicle protein 2A. Some antiepileptics have multiple mechanisms of action.¹¹⁴

During seizures, a high-frequency pattern of neuronal firing is detected. This pattern is uncommon during normal physiologic neuronal activity. Voltage-gated sodium channels (VGSCs) are primarily responsible for this rapid neuronal firing. Under the influence of sodium channel blockers, the VGSCs are maintained partially open with their internal inactivation gates closed. The VGSCs cannot recover from inactivation and are prevented from firing repetitively. Phenytoin, carbamazepine, VPA, lamotrigine, topiramate, oxcarbazepine, and zonisamide all attach themselves to the batrachotoxin binding site (or adjacent area) on the VGSCs, close the inactivation gate, and prolong the recovery from inactivation.^{113,114,194,198} At therapeutic concentrations, VGSC binding is largely selective. At toxic concentrations, selectivity is lost, and both high-frequency and spontaneous sodium channels are inhibited, including those found in cardiac tissue responsible for action potential initiation leading to electrocardiographic (ECG) disturbances such as QRS complex prolongation and atrioventricular blockade.^{27,50,92,127,173,178} Lacosamide is unique as it binds to collapsing response mediator protein 2 (CRMP-2), a phosphoprotein in the VGSC, and slows inactivation of the channel resulting in limited repetitive firing.¹¹⁴

Voltage-gated calcium channels (VGCCs) are multisubunit complexes that are broadly classified into low- and high-voltage groups. The low voltage group encompasses the T-type calcium channels. Zonisamide, VPA, and ethosuximide inhibit flow of calcium through these channels, thus reducing the T current, also known as the pacemaker current.^{136,145} Gabapentin and pregabalin bind to the $\alpha_2\delta_1$ subunit of the presynaptic P/Q VGCC, reducing the calcium required fusion of synaptic vesicles to membranes and reducing the exocytosis of glutamate.¹¹⁴ Levetiracetam inhibits N-type calcium channels, but this is not its major mechanism of action.^{107,109}

The N-methyl-D-aspartate (NMDA) receptor is the glutamate receptor of greatest clinical importance with respect to development of seizures. When stimulated by glutamate, the NMDA receptor activates a ligand-gated ion channel that

permits entry of Na⁺ and Ca²⁺ into the neuronal cells. Suppression of the glutamate–NMDA interaction is protective against seizures.¹¹⁴ VPA is a possible competitive glutamate antagonist at the NMDA receptors. Lamotrigine and possibly high dose phenytoin inhibit glutamate release by binding to presynaptic Na⁺ channels.⁵⁷ Topiramate binds to kainate, as opposed to the NMDA glutamate receptor, and blocks Na⁺ entry into the neuronal cell.¹⁴⁰

GABA acts through fast chloride-permeable ionotropic GABA_A receptors and slower G protein–coupled GABA_B receptors. The recently discovered GABA_c receptors are not well studied. Vigabatrin irreversibly inhibits GABA transaminase, the enzyme primarily responsible for GABA metabolism.^{71,114} VPA may have similar effects.¹¹⁴ Tiagabine inhibits the GABA transporter GAT-1 and thereby prevents reuptake of GABA into presynaptic neurons.^{71,114} Neither gabapentin nor pregabalin, despite their structural similarity to GABA, mimics GABA when iontophoretically applied to GABA neurons.^{114,118}

Lastly, synaptic vesicular 2A (SV2A) proteins are members of the superfamily of proteins called membrane transporters that are an integral part of secretory vesicles in neuronal tissue. Levetiracetam binds with high affinity to SV2A, inducing a conformational change in the protein that leads to inhibition of vesicular exocytosis from the presynaptic neuron.^{74,109} Table 48–1 and Figure 48–1 summarize these findings.

TABLE 48–1. Comparison of Mechanisms of Action of Antiepileptics

Sodium Channel Inhibition	NMDA/Kainate Inhibition
Carbamazepine	Lamotrigine
Lacosamide	Topiramate
Lamotrigine	?High-dose phenytoin
Oxcarbazepine	?Valproic acid
Phenytoin (fosphenytoin)	GABA Related
Topiramate	Tiagabine
Valproic acid	Vigabatrin
Zonisamide	SV2A Related
Calcium Channel Inhibition	Levetiracetam
Gabapentin	
Ethosuximide	
Pregabalin	
Valproic acid	
Zonisamide	

GABA = γ-aminobutyric acid; NMDA = *N*-methyl-D-aspartate.

FIGURE 48–1. The mechanisms of action of anticonvulsants can generally be placed into one of four categories: sodium or, calcium channel inhibition, inhibition of excitatory aminoacids GABA agonism and inhibition of presynaptic vesicular exocytosis. GABA = γ -aminobutyric acid; GABA-T = GABA transaminase; NMDA = N-methyl-D-aspartate; SAS = succinic acid semialdehyde.

CARBAMAZEPINE

Carbamazepine is structurally related to the cyclic antidepressants. It is a narrow spectrum antiepileptic. Carbamazepine is a first-line agent for seizures and is a pregnancy category D medication associated with kinked ribs and cleft palate.^{16,50}

Pharmacokinetics and Toxicokinetics

Carbamazepine is lipophilic, with slow and unpredictable absorption after oral administration and rapid distribution to all tissues. Peak concentrations are reached as late as 12 to 24 hours after ingestion, especially after large ingestion of sustained-release preparations.¹⁹⁹ Carbamazepine also possesses weak anticholinergic properties and can decrease gastrointestinal (GI) motility, delaying its own absorption. Hence, no simple relationship exists between the dose and the serum concentration of carbamazepine.

Carbamazepine is metabolized primarily by CYP3A4 to carbamazepine 10,11-epoxide, which is pharmacologically active. This quantifiable metabolite is further degraded by epoxide hydrolase to carbamazepine-diol, a largely inactive compound.⁸³ Elimination of carbamazepine increases over the first few weeks of therapy because of autoinduction, and the half-life during chronic therapy shortens substantially. Therefore, the dose must be increased gradually over a 2- to 4-week period to a final daily dose of 10 to 20 mg/kg for adults and 20 to 70 mg/kg for children. Children require a higher dose because they eliminate the drug more rapidly. During chronic therapy, the elimination half-life ranges from 10 to 20 hours.⁹⁸ Furthermore, at very high serum concentrations, zero-order elimination kinetics are observed¹⁹⁹ (Tables 48–2 and 48–3).

TABLE 48–2. Pharmacokinetics of Antiepileptics after Therapeutic Oral Administration

	Time to Max Serum Concentration (hours)	Therapeutic Serum Concentration		Volume of Distribution (L/kg)	Protein Binding (%)	Urinary Elimination Unchanged (%)	Active Metabolite	Elimination Half-Life (hours)
		(mg/L)	(μ mol/L)					
Carbamazepine	3–24 in overdose	4–12	17–51	0.8–1.8	75	1–2	CBZ 10, 11-epoxide	Acute, 6–20; chronic, 5–12

Clinical Manifestations

Acute carbamazepine toxicity is characterized by neurologic signs and symptoms in association with cardiovascular effects. The initial neurologic disturbances include nystagmus, ataxia, and dysarthria. In patients with a large overdose, fluctuations in level of consciousness and coma are observed.^{68,154,159} Carbamazepine toxicity may cause seizures both in nonepileptic and epileptic patients.^{24,108} The mechanism underlying carbamazepine-induced seizures is poorly understood.^{68,136} In some cases, an increase in seizure frequency, unaccompanied by other neurologic effects, is the

presenting symptom of carbamazepine toxicity. Status epilepticus may complicate acute carbamazepine toxicity.¹⁷⁰ In a large case series, 55% of adult patients with carbamazepine concentrations greater than 40 mg/L developed seizures.⁶⁸ Children may experience seizures at lower concentrations.¹⁶⁹

Cardiovascular effects include sinus tachycardia, which occurs in 35% of overdoses as a result of an anticholinergic mechanism, hypotension with myocardial depression, and cardiac conduction abnormalities.⁶⁸ High concentrations of carbamazepine may cause depression of phases 0, 2, and 4 of the cardiac action potential ([Chap. 16](#)).¹⁷³ In a large case series of carbamazepine overdoses, a 15% incidence of QRS complex prolongation (>100 msec), 50% incidence of QT interval prolongation (>420 msec), and no cases of terminal 40 msec axis deviation of the QRS complex in limb leads were observed.⁶ These abnormalities can be delayed for as long as 20 hours and may occur with chronic therapy.^{6,76} The toxicity of carbamazepine in children differs slightly from that in adults. Children experience a higher incidence of dystonic reactions, choreoathetosis, and seizures and have a lower incidence of ECG abnormalities.^{169,177} Chronic carbamazepine overdose can result in headaches, diplopia, or ataxia. Idiosyncratic adverse events are common.¹⁵¹

The incidence of carbamazepine induced hyponatremia ranges from 1.8% to 40%. Increased antidiuretic hormone secretion (SIADH) or increased sensitivity of peripheral osmoreceptors to antidiuretic hormone are suggested mechanisms^{93,114} ([Chap. 19](#)).

Diagnostic Testing

Serum carbamazepine concentrations should be obtained in all cases of carbamazepine exposure. Because of erratic absorption, the concentrations should be repeated every 4 to 6 hours and closely monitored until a downward trend is observed. In one case report, peak concentrations were reached 106 hours after ingestion in a patient who ingested a sustained-release preparation.²⁴ Serum concentrations greater than 40 mg/L are associated with coma, seizures, respiratory depression, and cardiotoxicity.¹ Carbamazepine may cross-react with toxicology screening for tricyclic antidepressants ([Chap. 71](#)).⁴⁸

Patients receiving multiple antiepileptics, especially combination therapy with VPA and lamotrigine, may develop carbamazepine toxicity at serum concentrations within the therapeutic reference range because of elevated concentrations of the circulating carbamazepine-10,11-epoxide metabolite ([Table 48–4](#)). This finding is attributed to the additive inhibitory effects of VPA and lamotrigine on the enzyme epoxide hydrolase. Carbamazepine-10,11-epoxide concentrations in the 1 to 10 mg/L range are detected.

TABLE 48–4. Antiepileptic Drug Interactions

	Toxicity Increased by	Anticonvulsant Effect Decreased by	Increases Concentrations of	Decreases Concentrations of
Carbamazepine	Allopurinol, amiodarone, cimetidine, danazol, diltiazem, fluoxetine, fluvoxamine, gemfibrozil, INH, ketoconazole, lamotrigine, macrolides, nefazodone, nicotine, propoxyphene, protease inhibitors, verapamil	Benzodiazepines, felbamate, isotretinoin, phenobarbital, phenytoin, primidone, succinimides, VPA	None	Doxycycline, felbamate, haloperidol, lamotrigine, methadone, OCPs, phenytoin, primidone, tiagabine, VPA, warfarin
Gabapentin	Cimetidine	Antacids	Felbamate	None
Lamotrigine	Sertraline, VPA	Antituberculous medications, CBZ, phenobarbital, phenytoin	CBZ epoxide	None
Levetiracetam	None	None	Phenytoin	None
Oxcarbazepine	None	CBZ, phenobarbital, phenytoin	Phenytoin	Lamotrigine, OCPs
Phenytoin	Allopurinol, amiodarone, chloramphenicol, chlorpheniramine, clarithromycin, cloxacillin, cimetidine, disulfiram, ethosuximide, felbamate, fluconazole, fluocuracil, fluoxetine, fluvoxamine, imipramine, INH, methylphenidate, metronidazole, miconazole, omeprazole, phenylbutazone, sulfonamides, ticlopidine, trimethoprim, tolbutamide, tolazamide, topiramate, VPA, warfarin	Antacids, antineoplastics CBZ, calcium, diazepam, diazoxide, ethanol (chronic), folic acid, influenza vaccine, loxapine, nitrofurantoin, phenobarbital, phenylbutazone, pyridoxine, rifampin, salicylates, sulfisoxazole, sucralose, theophylline, tolbutamide, VPA, vigabatrin	Phenobarbital, primidone, warfarin	Amiodarone, CBZ, cardioactive steroids, corticosteroids, cyclosporine, disopyramide, dopamine, doxycycline, furosemide, haloperidol, influenza vaccine, levodopa, methadone, mexiletine, OCP phenothiazines, quinidine, tacrolimus, theophylline, tiagabine, tolbutamide, VPA
Tiagabine	None	CBZ, phenobarbital, phenytoin	None	VPA
Topiramate	None	CBZ, phenobarbital, phenytoin	Phenytoin	OCPs, digoxin

Vigabatrin	None	None	None	Phenytoin
Zonisamide	None	CBZ, phenobarbital, phenytoin	TCBZ	TCBZ

CBZ = carbamazepine; INH = isoniazid; OCP = oral contraceptive; VPA = valproic acid.

Management

Multiple-dose activated charcoal (MDAC) reduces enterohepatic and enteroenteric circulation of carbamazepine.^{15,108,162} In a randomized trial, MDAC was associated with a reduction in the elimination half-life of carbamazepine from 28 to 13 hours, a decrease in need for mechanical ventilation, a shorter coma, and a shorter length of stay in the intensive care unit (ICU).¹⁵ Cardiac monitoring for occurrence of QRS or QT abnormalities is recommended for all patients. Although not formally studied, sodium bicarbonate should be administered if the QRS duration exceeds 100 msec. Carbamazepine-induced seizures are treated with benzodiazepines. Hemodialysis (HD) is relatively ineffective for removal of carbamazepine, mostly because it is poorly water soluble. One study observed increased clearance with HD supplemented with albumin dialysate.³¹ Charcoal hemoperfusion, if available, will increase carbamazepine clearance and may be a useful adjunct in life-threatening overdoses.^{108,138} Continuous venovenous HD and hemodiafiltration were used successfully in a few patients but had no significant effect in others.^{8,64,160,163,201} It must be emphasized that MDAC remains effective in decreasing concentrations, is universally available, is much less invasive, and is associated with good clinical outcomes.^{15,160}

GABAPENTIN

Gabapentin is a narrow-spectrum antiepileptic that has achieved greater popularity as an adjunctive therapy for chronic pain.⁵⁰ It has high water solubility but poor lipid.¹⁷ It is a category C medication with limited human data in pregnancy.¹⁶

Pharmacokinetics and Toxicokinetics

The bioavailability of gabapentin is approximately 60% in the therapeutic dose range. Absorption kinetics are dose dependent with decreasing bioavailability at increased dosage because of saturation of the L-amino acid transport system. Dosage adjustments are necessary in patients with creatinine clearance of 60 mL/min or less. It is not metabolized by and does not affect the CYP450 system and has no significant interactions with other antiepileptics¹¹⁴ (Table 48–3).

Clinical Manifestations

Sedation, ataxia, movement disorders, slurred speech, and GI symptoms are observed after acute gabapentin overdose.^{65,88,141,191} In a case series of 20 patients with gabapentin overdose, lethargy, ataxia, and GI symptoms developed in less than 5 hours and resolved within 4 to 24 hours.⁸⁸ Catatonia after abrupt withdrawal of gabapentin is described.¹⁴⁹

Diagnostic Testing

Effective control of seizures typically occurs at concentrations above 2 mg/L. Because of its large therapeutic index, monitoring of serum gabapentin concentrations may not be necessary.⁹¹

Management

The treatment is largely supportive. The rapid saturation of the transporter system limits bioavailability and absorption in large overdoses. Patients with persistent neurologic symptoms should be admitted to the hospital. HD and hemoperfusion are not generally necessary, but up to 35% is removed by HD in anuric patients.^{41,69}

LACOSAMIDE

Lacosamide is a functionalized amino acid approved for use since 2008. Because of its high water solubility, it was developed for intravenous (IV) and oral use.⁹² It is a category C medication with limited data in human pregnancy.¹⁶

Pharmacokinetics and Toxicokinetics

Lacosamide has a favorable pharmacokinetic profile. It is predominantly excreted unchanged in the urine and undergoes only minor hepatic metabolism (CYP2C19). It displays no significant pharmacokinetic medication interactions, contrary to many other antiepileptics that block VGSC.¹²⁸

Clinical Manifestations

One case report of therapeutic error in IV administration of lacosamide resulted in reversible atrioventricular heart block.²¹ Data suggest a pharmacodynamic interaction between lacosamide and other VGSC blockers.¹²⁸ Chronic lacosamide along with other VGSC blockers is associated with ataxia, diplopia, and sedation.¹²⁸

Management

Activated charcoal (AC) should be considered. ECG monitoring and supportive care is recommended.

LAMOTRIGINE

Clinical Manifestations

Lamotrigine, a broad-spectrum antiepileptic, is approved as an adjunctive medication for treatment of seizures in adults and children. It also is approved for maintenance treatment of bipolar mood disorder. It is a category C medication with limited human data in pregnancy.¹⁶

Pharmacokinetics and Toxicokinetics

The bioavailability of lamotrigine is 98%. It is predominantly glucuronidated to lamotrigine 2-N-glucuronide. The elimination half-life is approximately 25 hours but can be halved in the presence of phenytoin and carbamazepine and doubled in the presence of VPA. Phenytoin and carbamazepine induce glucuronidation. VPA competes with lamotrigine for the same step in the glucuronidation process. Significantly reduced clearance of lamotrigine occurs in patients with Gilbert syndrome (syndrome of defective glucuronidation). Lamotrigine does not affect the CYP450 system or the metabolism of other medications except when it is administered concomitantly with carbamazepine, when it is associated with accumulation of the carbamazepine epoxide metabolite.⁵⁷

Clinical Manifestations

Neurologic manifestations such as lethargy, ataxia, nystagmus, and GI symptoms are described after lamotrigine overdose. Coma, hypokinesia, seizures, status epilepticus, hypertension, tachycardia, and cardiac conduction disturbances may occur.^{103,121} Cardiac conduction abnormalities including QRS complex prolongation, Brugada-like ECG abnormalities, and

third-degree heart block are all related to sodium channel blockade.^{27,50,127,178}

Chronic supratherapeutic dosing resulted in oculoerythric crises in four patients.¹⁹⁰ Chronic therapy is associated with rashes, rhabdomyolysis, elevated hepatic aminotransferases, and serum creatinine phosphokinase concentrations, findings suggestive of a hypersensitivity reaction.¹⁴⁷

Diagnostic Testing

Lamotrigine concentrations greater than 14 mg/L are potentially toxic.

Management

Activated charcoal should be administered. Supportive care and ECG monitoring are recommended. Lamotrigine-induced seizures respond to benzodiazepines.^{22,39,186,195} Data on HD and hemoperfusion are not available, but based on its size, relatively low protein binding, and volume of distribution (1.4 L/kg), lamotrigine should be removed by HD. IV fat emulsion was used successfully in two severe cases of lamotrigine poisoning presenting with coma, seizures, and QRS complex widening.^{27,121} (Antidotes in Depth: A20).

LEVETIRACETAM

Levetiracetam is a broad-spectrum antiepileptic with a wide margin of safety in administration and very favorable pharmacokinetics.⁶³ It is a category C medication with limited human data in pregnancy.¹⁶

Pharmacokinetics and Toxicokinetics

The bioavailability of levetiracetam approaches 100%. The major metabolic pathway involves enzymatic hydrolysis of the acetamide group. This reaction is not dependent on hepatic CYP450 activity. There are no active metabolites. Dosage adjustments are necessary in patients with creatinine clearances of 60 mL/min or less.⁷¹

Clinical Manifestations

Mild central nervous system (CNS) depression, vertigo, and ataxia were reported in one large case series.¹³ Respiratory depression was observed in one case report.¹¹ Two case reports of children with supratherapeutic dosing noted only mild effects such as slight decrease in muscle tone, which reversed immediately after the doses were adjusted.⁹

Diagnostic Testing

Therapeutic concentrations are 10 to 40 µg/mL. Because of its large therapeutic window, routine monitoring of serum levetiracetam concentrations may not be necessary.⁷¹

Management

Activated charcoal should be considered. Supportive care is recommended.

OXCARBAZEPINE

Oxcarbazepine is an analog of carbamazepine that functions as a prodrug. Presystemic 10-ketoreduction rapidly metabolizes oxcarbazepine to monohydroxy carbamazepine (MHD), which is pharmacologically active.¹¹⁴ MHD is subsequently conjugated and renally eliminated. It is a less potent inducer of CYP3A4 than carbamazepine and has minimal effects on its own metabolism.¹¹⁴ It is a category C medication with limited data in human pregnancy.¹⁶ CNS depression and possibly bradycardia and hypotension are reported after overdose.^{135,189} In these cases, serum oxcarbazepine concentrations reached 7 to 32 mg/L (therapeutic, <3 mg/L), yet concentrations of MHD were 46 to 65 mg/L (therapeutic, 10–35 mg/L), less than twofold the therapeutic concentrations. The formation of MHD is a rate-limited process, and this probably contributes to the relatively low MHD concentrations after acute oxcarbazepine overdose.^{53,135,189}

Activated charcoal should be administered, and supportive care should be provided. The rate-limited enzymatic conversion from inactive prodrug to active metabolite may limit its toxicity. HD does not increase the clearance of oxcarbazepine or its metabolite and is not useful.⁵³

PHENYTOIN AND FOSPHENYTOIN

Phenytoin is still widely considered a first-line antiepileptic for the treatment of most seizure disorders except absence seizures. It is a narrow-spectrum antiepileptic that is nonsedating in therapeutic doses and therefore often used successfully for long-term management of epilepsy.⁵⁰ Phenytoin, a pregnancy category D drug, is associated with the fetal hydantoin syndrome and possible hemorrhage at birth.¹⁶

Introduced in 1997, fosphenytoin is a water-soluble phosphate ester prodrug of phenytoin. Advantages include availability for intramuscular (IM) administration and low potential for tissue injury at injection sites.^{18,114}

Pharmacokinetics and Toxicokinetics

Phenytoin is rapidly distributed to all tissues following a two-compartment model. In patients with nondetectable phenytoin serum concentrations, oral loading doses of 20 mg/kg yield therapeutic (>10 mg/L) serum concentrations at 5.6 ± 0.2 hours.¹⁸¹ In cases of very large oral overdoses, GI absorption can be delayed because of capacity limited absorption or decreased GI motility, and peak serum concentrations may take days to be reached.^{28,33} Some authors suggest that phenytoin absorption may continue in the colon because of its lipophilic properties.¹⁷⁵ Additionally, phenytoin occasionally forms concretions in the GI tract.^{28,33}

Phenytoin is extensively bound to serum proteins, mainly albumin. Only the unbound free fraction can cross biologic membranes and is pharmacologically active. A significant fraction of phenytoin remains unbound in neonates, uremic patients, and other patients with hypoalbuminemia, such as patients in ICUs.^{37,61}

Less than 5% of a given dose of phenytoin is excreted unchanged in the urine. The remainder is metabolized in the liver. The major phenytoin metabolite, a parahydroxylphenyl derivative, is inactive but is the putative metabolite responsible for the hypersensitivity reaction associated with phenytoin administration.⁹⁰ The Michaelis-Menten model of saturable enzyme kinetics explains the relationship between phenytoin doses and serum concentrations at steady state. At phenytoin concentrations below 10 mg/L, elimination usually is first order, and elimination half-life ranges between 6 and 24 hours. At higher concentrations, zero-order elimination occurs as a result of saturation of the hydroxylation reaction, and the apparent elimination half-life increases to 20 to 60 hours.¹¹⁴ Therefore, the apparent half-life of elimination of phenytoin is progressively prolonged as plasma concentration increases (Chap. 9).

Fosphenytoin is a prodrug. It is metabolized by tissue and blood phosphatases to phenytoin, phosphate, and formaldehyde. The bioavailability of the derived phenytoin is 100% when compared with intravenously administered phenytoin regardless of the route of administration (IV or IM). The half-life of conversion of fosphenytoin to phenytoin is 7 to 15 minutes. Faster rates of IV infusion and displacement of phenytoin from protein binding sites by fosphenytoin compensate for the conversion-related delay in appearance of phenytoin in serum.⁴⁷ The dose of fosphenytoin is expressed in phenytoin equivalents (PEs).

Clinical Manifestations

Acute phenytoin toxicity produces predominantly neurologic dysfunction that typically affects the cerebellar and vestibular systems. Phenytoin concentrations greater than 15 mg/L usually are associated with nystagmus; concentrations greater than 30 mg/L are associated with ataxia and poor coordination; and concentrations exceeding 50 mg/L are associated with lethargy, slurred speech, and pyramidal and extrapyramidal manifestations.^{33,119} Toxic concentrations rarely cause de novo seizures.¹⁷⁶ Young children and elderly adults may present with atypical manifestations of toxicity. Decreased appetite, poor feeding, diminished activity, abdominal distension, chorea, and opisthotonic posturing are reported after oral overdoses in infants.¹⁰⁵

Cardiotoxicity resulting from oral overdoses of phenytoin is almost never reported.^{44,179} However, IV phenytoin impairs myocardial contractility, decreases peripheral vascular resistance, and depresses myocardial conduction. In a large case series, IV phenytoin was associated with a 3.5% incidence of hemodynamic complications.⁴³ Deaths after IV administration of phenytoin are reported.^{58,152,193,203} Hypotension, dysrhythmias, and cardiac arrest are associated with higher rates of infusion and higher infused doses. All can be at least partially attributed to the propylene glycol (40%) and ethanol (10%), the diluents used in the IV preparation of phenytoin.¹²⁰ Propylene glycol in particular depresses myocardial tissue and decreases peripheral vascular resistance (Chap. 55). Fosphenytoin, available only as a parenteral preparation, does not contain propylene glycol, but the metabolism of this prodrug releases phosphate and formaldehyde. Two reports describe bradycardia, hypotension, and asystole when, five- to 10-fold overdoses of fosphenytoin were administered to infants in error.^{96,148} One infant had a serum phenytoin concentration of 77.2 mg/L and marked hyperphosphatemia (serum phosphate concentration of 25.9 mg/L), although the serum calcium, magnesium, and blood urea nitrogen were normal.¹⁴⁸ Others report hyperphosphatemia after the administration of fosphenytoin to a patient with end-stage kidney disease.¹¹² Another report describes hypocalcemia and prolongation of the QT interval after the administration of fosphenytoin (1500 mg PE) intravenously to an adult patient with normal kidney function; however, no phosphate measurements were obtained.⁸²

Serious soft tissue reactions such as the purple glove syndrome can occur after administration of IV phenytoin and are not always related to problematic infusions or extravasation. The incidence of the purple glove syndrome ranges from 1.7% to 6%.^{21,129} Symptoms begin 2 to 12 hours after administration and include discoloration, edema, and possible blistering distal to the site of administration.²¹ Symptoms may be mild and resolve over days to weeks or may be severe and lead to necrosis, possibly necessitating amputation of digits.^{21,34,43,86,156} The risk of fosphenytoin-induced skin necrosis is lower because of its water solubility.

Chronically elevated phenytoin concentrations may result in gingival hyperplasia, frontal bossing, pseudolymphoma cerebellar effects, behavioral changes, and encephalopathy. Hyperactivity, confusion, lethargy, and hallucinations characterize the behavioral changes. Chronic use of phenytoin is associated rarely with agranulocytosis. Phenytoin may produce hepatotoxicity.

Diagnostic Testing

Serum phenytoin concentrations should be obtained in all cases of phenytoin exposure. Because of unpredictable absorption, phenytoin concentrations should be repeatedly monitored. Therapeutic concentrations are 10 to 20 mg/L. Because of zero-order elimination, high serum phenytoin concentrations may take days or weeks to return to the therapeutic range.^{33,105,119}

Patients with impaired or decreased protein-binding capacity can develop symptoms at total phenytoin concentrations within the therapeutic range. Patients at greatest risk include neonates; elderly adults; hypoalbuminemic, hyperbilirubinemic, and uremic patients; and patients undergoing combination therapy with VPA, salicylates, and sulfonamides because these agents displace phenytoin from its albumin binding sites. In such patients, determination of the free phenytoin concentration is helpful because it compares more reliably with the cerebrospinal fluid concentrations than does the total phenytoin concentration.³⁷ Therapeutic free phenytoin concentrations are 1.0 to 2.1 mg/L.¹⁴

Equation 48–1 approximates the total phenytoin concentration that would be expected on a given measured serum phenytoin concentration and measured albumin concentration.³⁴

$$[\text{Phenytoin}] = \frac{[\text{Measured phenytoin}]}{(0.25 \times [\text{Measured albumin}]) + 0.1} \quad (\text{Eq. 48-1})$$

Management

The treatment of patients with acute or chronic phenytoin overdoses remains largely supportive. Phenytoin-related deaths are rare, even after massive overdoses. MDAC reduces the elimination half-life of intravenously administered phenytoin from 44.5 to 22.3 hours. MDAC also decreased serum concentrations of phenytoin significantly more rapidly than no MDAC in patients with supratherapeutic concentrations from chronic overdose who were randomized to either therapy.¹⁶⁷ HD was performed in four cases of acute phenytoin overdoses and was associated with 3% to 92% reductions in serum concentrations. In only two of the four cases did significant clinical improvement follow HD.^{55,150,161,185} Charcoal hemoperfusion, plasmapheresis, and other extracorporeal techniques such as molecular adsorbents recirculating systems (MARS) are of marginal benefit in the management of phenytoin overdose and are not associated with improved outcomes.^{37,79,119,158} Extracorporeal drug removal is rarely indicated in phenytoin overdoses but may be considered in patients presenting with persistent coma and significantly elevated serum concentrations. All patients admitted to the hospital for phenytoin overdose require neurologic assessments; those who are admitted after an oral exposure do not require routine cardiac monitoring because they do not usually experience dysrhythmias or cardiovascular complications.^{44,105,179} Phenytoin-induced agranulocytosis can be treated successfully with administration of granulocyte colony-stimulating factor.¹⁸⁰

Hypotension, cardiac dysrhythmias, and dyskinesias during IV administration of phenytoin are generally transient and usually resolve in 30 to 60 minutes unless complications occur. Stopping the phenytoin infusion for a few minutes and administering a bolus of 250 to 500 mL of 0.9% sodium chloride solution generally is sufficient to treat the hypotension. Restarting the infusion at half the initial rate is recommended.

Electrocardiographic abnormalities, especially a prolonged QT interval temporally related to fosphenytoin infusions, may be due to hyperphosphatemia and hypocalcemia, and these electrolyte abnormalities should be rapidly corrected. In one case, HD was required to correct the hyperphosphatemia.¹¹² Life-threatening dysrhythmias may require prolonged periods of cardiopulmonary resuscitation.^{96,148}

The management of extravasation is discussed in Special Considerations: SC4.

PREGABALIN

Pregabalin is a second-generation narrow-spectrum antiepileptic agent developed as a more potent analog of gabapentin. It is indicated in the management of epilepsy and neuropathic pain.¹⁵⁵ It has high water solubility and poor lipid solubility.¹⁷

Pharmacokinetics and Toxicokinetics

Pregabalin, contrary to gabapentin, does not have a saturable GI transporter protein and is highly bioavailable with rapid absorption. It is not protein bound, and more than 90% of the medication is excreted unchanged in the urine.¹⁴² Its elimination half-life, similar to that of gabapentin, is short, 4.6 to 6.9 hours. Pregabalin has no significant interactions with other antiepileptic agents except perhaps increasing the steady-state concentrations of tiagabine.¹⁷ It is a category C medication with limited human data in pregnancy.¹⁶

Clinical Manifestations

Overdose experience is limited. Drowsiness, dizziness, tremors, muscle twitching, and seizures are described after overdose.^{131,166} One patient developed third-degree atrioventricular block perhaps because of blockade of L-type calcium channels in the myocardium.¹ Peripheral edema, weight gain, and decompensated congestive heart failure occur after chronic therapy.¹²³

Diagnostic Testing

The proposed therapeutic concentrations are 2.8 to 8.3 mg/L.

Management

Administration of AC is recommended. Pregabalin is cleared by HD.^{91,202}

TIAGABINE

Tiagabine inhibits GABA reuptake and is approved as an adjunctive treatment of seizures. It is also prescribed for a variety of psychiatric disorders. Tiagabine is a narrow-spectrum antiepileptic medication.⁵⁰ It is a category C medication with limited data in human pregnancy.¹⁶

Pharmacokinetics and Toxicokinetics

Tiagabine is quickly and completely absorbed within 2 to 3 hours of ingestion. It is widely distributed and easily crosses the blood-brain barrier.⁸⁷ It is metabolized by the CYP3A4 system to inactive metabolites. The elimination half-life is reduced by 50% in patients taking enzyme-inducing antiepileptics.¹⁰⁶ It has no effect on the CYP450 system.¹⁰⁶

Clinical Manifestations

Lethargy, facial myoclonus (grimacing), nystagmus, and posturing are described in patients who overdose on tiagabine.^{26,171} Seizures and status epilepticus are reported at therapeutic doses as well as in overdose.^{52,70,81,132} One previously healthy girl developed multiple seizures after an unsupervised ingestion of tiagabine.⁸¹ A patient presented in status epilepticus and was believed to be noncompliant with therapy until a tiagabine concentration of 1.87 mg/L was obtained and an acute overdose confirmed.¹³² Stimulation of the presynaptic GABA_B receptors in the thalamus is suggested as the underlying mechanism for tiagabine-induced seizures.¹⁴⁴ Symptoms generally persist for 12 to 24 hours, and permanent neurologic sequelae usually do not occur.^{26,81,132,171}

Diagnostic Testing

Therapeutic tiagabine concentrations are 5 to 70 ng/mL.

Management

Activated charcoal and supportive care are recommended. Seizures respond to administration of benzodiazepines even though the beneficial effects of the GABA agonists such as benzodiazepines seem paradoxical when treating seizures from tiagabine.^{52,70,81,132} Status epilepticus resistant to benzodiazepines should be treated with barbiturates or propofol. Posturing and grimacing are treated with benzodiazepines.²⁶ Data on the use of HD and hemoperfusion are not available, but because of high protein binding, HD will likely not be effective.

TOPIRAMATE

Topiramate is approved as adjunctive therapy for seizures in adults. It is also approved for migraine prophylaxis, infantile spasms, IHH, and other refractory seizure disorders in infants and children. Topiramate is a broad-spectrum antiepileptic. Its sulfamate moiety weakly inhibits carbonic anhydrase, specifically the carbonic anhydrase II and IV isoforms present in the kidneys and CNS.⁴⁰ Topiramate is a pregnancy category D drug because of the risk of oral clefts.

Pharmacokinetics and Toxicokinetics

Topiramate is readily bioavailable. Only 20% of the dose is hepatically metabolized via hydroxylation, hydrolysis, and glucuronidation; the remaining 80% of the medication is eliminated unchanged in the urine (Table 48–2).

Clinical Manifestations

Lethargy, ataxia, nystagmus, myoclonus, hallucinations, coma, seizures, and status epilepticus are all reported after topiramate overdose.^{32,46,101,103,168} Lethargy may be accompanied by abnormal speech patterns, such as echolalia, and word-finding difficulties after acute overdose.^{32,187} In some cases, the clinical effects lasted for days.¹⁰¹ Hyperchloremic metabolic acidosis resulting from inhibition of renal cortical carbonic anhydrase may be present (lowest reported bicarbonate concentration, 12 mEq/L) along with hypocitraturia and high urine pH leading to formation of calcium phosphate stones.⁵⁸ The hyperchloremic metabolic acidosis typically appears within hours of ingestion and can also persist for days.^{32,46,137,187} Clinical effects, especially seizures, mostly occur in acute overdoses and not in acute-on-chronic overdoses or during dose escalation.^{113,115,200}

Diagnostic Testing

A death with a postmortem concentration of 170 mg/L is reported.⁹⁵ Serum chemistry or arterial blood gas analysis should be adequate to evaluate for hyperchloremia, hypokalemia, and metabolic acidosis.

Management

Activated charcoal and supportive care are recommended. Severe hyperchloremic metabolic acidosis should be treated with sodium bicarbonate 1 to 2 mEq/kg intravenously. However, systemic administration of sodium bicarbonate may impair the anticonvulsive effect of topiramate and sodium might increase calcium excretion.^{32,46,58} HD can increase topiramate clearance four- to sixfold.⁵⁴ HD is generally recommended in patients with life-threatening topiramate overdoses presenting with significant neurologic impairment, intractable electrolyte abnormalities, or anuria. Recurrent calcium phosphate stones should be treated with an increase in urine volume, restriction of sodium intake, and possible supplementation with potassium citrate.⁵⁸

VALPROIC ACID

Valproic acid (di-n-propylacetic acid {VPA}) is a simple branched chain carboxylic acid that is used for treatment of seizure disorders, mania associated with bipolar disorder, and in migraine prophylaxis. VPA is a broad-spectrum antiepileptic. It is a category D drug in pregnancy and is associated with neural tube and facial defects.¹⁶

Pharmacokinetics, Toxicokinetics, and Pathophysiology

Valproic acid is well absorbed from the GI tract with a bioavailability of 80% to 90%. Peak concentrations usually are reached in 6 hours, except for enteric-coated and extended-release preparations, with which peaks are delayed for up to 24 hours.^{45,84,117} VPA is 90% protein bound at therapeutic concentrations, but the percentage decreases to 35% as the VPA concentration exceeds 300 mg/L because of saturation of binding sites.^{49,75} (Table 48–2).

Valproic acid is less than 3% excreted unchanged in the urine and undergoes extensive biotransformation in the liver. Hepatic metabolism is complex and uses the same enzymes and cofactors that are needed for mitochondrial lipid metabolism. Glucuronidation, mitochondrial β -oxidation, and cytosolic β -oxidation account for 50%, 40%, and 10%, respectively, of the metabolism of VPA.¹⁶⁴ β -Oxidation occurs in the mitochondrial matrix and starts with passive diffusion of VPA across the double-layer mitochondrial membrane and ends with the transport of metabolites in the opposite direction using acetylCoA and carnitine as transporters^{100,182} (Fig. 48–2 and Table 48–5).

β -Oxidation of VPA depletes carnitine stores through a number of different mechanisms. VPA increases carnitine excretion via formation of valproylcarnitine, which can be renally excreted. Second, valproylcarnitine inhibits the adenosine triphosphate (ATP)-dependent carnitine transporter located on the plasma membrane. Third, VPA metabolites trap mitochondrial CoA. Mitochondrial CoA trapping (or depletion) decreases ATP production, which in turn negatively affects the carnitine transporter.^{100,143} Depletion of carnitine and sequestration of the limited pool of mitochondrial free acetyl-CoA are the end result of excessive β -oxidation.^{164,182} Reduced CoA activity decreases the formation of N-acetylglutamate, an obligatory cofactor for carbamoylphosphate synthetase I (CPS I). CPS I is the primary enzyme responsible for incorporation of ammonia into the urea cycle. The result is impaired ureogenesis and hyperammonemia. Ammonia can injure muscle and brain.^{10,190}

Mitochondrial dysfunction, inhibition of β -oxidation, and depletion of carnitine, acetylCoA, and possibly glutathione stores impair lipid metabolism and lead to fatty acid accumulation, steatosis, lysosomal leakage, formation of reactive oxygen species, and cytotoxicity histologically similar to Reye syndrome.^{139,164} This rare form of hepatotoxicity is often irreversible.¹⁶⁴

Lastly, a number of case reports describe an association between inborn errors of metabolism, seizure disorder, and VPA-induced hyperammonemia and hepatotoxicity after therapeutic dosing.¹⁶⁴

Clinical Manifestations

Overdoses of VPA result in symptoms varying from lethargy to coma associated with cerebral edema. In one large case series, 100% of patients with serum VPA concentrations greater than 850 mg/L manifested coma, 63% manifested respiratory depression requiring intubation and mechanical ventilation, and 25% developed hypotension.^{72,172}

Metabolic complications after acute VPA overdoses include hypernatremia, hypocalcemia, anion gap metabolic acidosis, and hyperammonemia.^{45,165,172} Anion gap metabolic acidosis after overdose is a poor prognostic sign. It results from accumulation of ketoacids and lactic acid, carboxylic, and propionic acid.^{5,35,62,146}

Bone marrow suppression occurs 3 to 5 days after acute massive overdoses of VPA and is characterized by pancytopenia.^{5,172} Hematopoietic disturbances usually resolve spontaneously within a few days.

Pancreatitis, hepatotoxicity, and acute kidney injury are rare manifestations of acute toxicity.^{5,35,85} Chronic VPA therapy may lead to hepatotoxicity and microvesicular steatosis secondary to the aforementioned metabolic aberration in fatty acid metabolism rather than, as with other antiepileptic agents, a hypersensitivity reaction.^{19,42} Clinical findings may vary from asymptomatic elevation of aminotransferase concentrations to fatal hepatitis.

Valproate-induced hyperammonemic encephalopathy is characterized by impaired consciousness with confusion or lethargy, focal or bilateral neurologic signs, and increased seizure frequency. It is not always accompanied by elevated VPA concentrations or hepatotoxicity.¹⁹⁶ The etiology is uncertain, but elevated ammonia concentrations coupled with elevated concentrations of some of the more neurotoxic VPA metabolites may be responsible.^{25,45,192} The differential diagnosis of acute hyperammonemia in the absence of liver disease includes urea synthesis errors, hematologic malignancies, VPA, 5-fluorouracil, and hyperalimentation.¹⁹⁶

Diagnostic Testing

Serum VPA concentrations should be obtained in all cases of VPA exposure and repeated every 4 to 6 hours until a downward trend is observed. Therapeutic concentrations are 50 to 100 mg/L, although some clinicians use higher concentrations.

Many VPA metabolites can be measured in the urine. In large overdoses, the 4-en-VPA concentration may be elevated, indicating a shift toward β -oxidation. The β -oxidation metabolite 2-en-VPA may be low or absent, indicating inhibition of β -oxidation or carnitine depletion. Concentrations of the 2-en-VPA metabolite increase 1 to 3 days after acute ingestion, signaling the return to normal β -oxidation.¹⁶⁴

Electrolytes, blood gases, liver function tests, platelets, and serum lactate and serum ammonia concentrations should be monitored in all patients. Hyperammonemia (>80 $\mu\text{g/dL}$ or >35 $\mu\text{mol/L}$) occurs in up to 80% of patients receiving chronic VPA therapy.¹⁶⁴

Management

Supportive management is sufficient to ensure complete recovery in most patients with VPA overdoses. Discontinuation of all medications that likely affect VPA metabolism is also recommended (Table 48-4).

MDAC is useful in preventing absorption of VPA, especially in overdoses of enteric-coated or extended-release preparations, but MDAC does not significantly affect the elimination of VPA.³ Naloxone does not reverse VPA-induced CNS depression or respiratory depression.^{29,73,188}

Carnitine should be administered if evidence indicates the presence of hyperammonemia or hepatotoxicity.^{77,99,182} Whereas IV carnitine is preferred in symptomatic patients, oral carnitine is sufficient in asymptomatic patients. The loading dose is 100 mg/kg IV over 30 minutes (maximum, 6 g) followed by 15 mg/kg IV over 10 to 30 minutes every 4 hours until clinical improvement occurs (Antidotes in Depth: A8).

Extracorporeal techniques appear to be somewhat useful in increasing elimination of VPA. In large overdoses, the free fraction of VPA is sufficiently high to allow for effective clearance by HD, and HD has reduced the elimination half-life of VPA to 2.5 hours in several cases.^{20,38,67,75,80,89,165} Charcoal hemoperfusion alone and in combination with HD was not superior to HD alone.^{49,110,165} Continuous venovenous hemodialfiltration did not significantly improve elimination in one patient.⁸⁰ HD remains the preferred modality of extracorporeal elimination of VPA. It should be considered for severe VPA overdoses presenting with coma or hemodynamic compromise and serum concentrations greater than 850 mg/L, particularly if severe hyperammonemia is present.⁴

VIGABATRIN

Vigabatrin, or vinyl GABA, is a stereospecific irreversible inhibitor of GABA-transaminase. Although vigabatrin has a short elimination half-life, its duration of action is 24 hours. Dosage adjustments are necessary in patients with creatinine clearance under 80 mL/min.¹¹⁴ It is a category C medication in pregnancy.¹⁶ Agitation, coma, and psychosis are reported after acute ingestion.^{36,97}

Chronic toxicity may result in dizziness, tremor, which usually is mild and transient, and depression and psychosis.⁹⁷ Treatment of vigabatrin toxicity is largely supportive. Severe agitation is best treated with benzodiazepines. Some cases of mild vigabatrin-induced psychosis resolve simply by withdrawal of the medication.⁹⁷ The use of vigabatrin is associated with a risk of retinopathy and visual peripheral field defects.¹⁵⁷

ZONISAMIDE

Zonisamide, a sulfonamide derivative with two decades of use in Japan, is an antiepileptic approved for adjunctive treatment of partial seizures in adults.¹¹⁴ Similar to topiramate, zonisamide also inhibits carbonic anhydrase enzymes.⁵⁸ It is a category C medication in pregnancy.¹⁶ Overdose experience with zonisamide is limited. In one case report, a patient who presented with obtundation, a QTc of 506 msec, and serum concentration of 182 mg/L (therapeutic, 10–40 mg/L) was intubated and placed on a ventilator and recovered in 3 days.⁶⁷ In another, a patient with a serum concentration of 110 mg/L received supportive care and recovered in 48 hours.¹⁹⁷ In one case report, status epilepticus, coma, and death were associated with zonisamide overdose despite a premortem concentration of 44 mg/L and presence of caffeine, diphenhydramine, and mirtazapine in postmortem heart blood.¹⁸³ Recurrence of calcium phosphate stones should be treated with an increase in urine volume, restriction of sodium intake, and possible supplementation with potassium citrate.⁵⁸

DRESS SYNDROME

Drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome, previously named drug hypersensitivity syndrome, is a severe adverse drug event first described in 1950.¹⁸⁴ DRESS syndrome is a distinct severe adverse drug reaction characterized by fever, rash, and solid organ involvement. DRESS syndrome occurs in approximately one of every 1000 to 10,000 uses of antiepileptics, usually aromatic antiepileptics such as phenytoin, carbamazepine, phenobarbital, primidone, and lamotrigine. The literature also supports the inclusion of oxcarbazepine and levetiracetam as causative antiepileptics.⁶⁰ Data suggest a genetic defect in drug metabolism as the causative lesion, for example HLA-A*3101 in Northern Europeans and Japanese individuals.¹³⁴ First-degree relatives of patients with DRESS have a 25% risk of developing this syndrome.^{90,192}

DRESS syndrome occurs most frequently within the first 2 months of therapy and is not related to dose or serum concentration. The pathophysiology is related to the accumulation of reactive arene oxide metabolites resulting from decreased epoxide hydrolase enzyme activity. These metabolites bind to macromolecules and cause cellular apoptosis and necrosis. They also form neoantigens that trigger T cell–mediated delayed (type IV) hypersensitivity reactions. Interestingly, the same metabolite is believed to cause other serious dermatologic reactions, such as Stevens-Johnson syndrome and toxic epidermal necrolysis¹⁷⁴ (Chap. 18 and Fig. 18–4).

Initial symptoms also include fever (>38.5°C); malaise; and pharyngitis, including tonsillitis. A macular exanthem that is very inflamed and covers more than 50% of the total body surface area, sparing the mucous membranes, is characteristic. Tender lymphadenopathy follows. Multiorgan involvement usually occurs 1 to 2 weeks into the syndrome. The liver is the most frequently affected organ (>80% of cases), although involvement of the CNS (encephalitis), heart (myocarditis), lungs

(pneumonitis), kidney (nephritis), and thyroid (hyperthyroid thyroiditis followed by hypothyroidism) are possible. Liver disturbances range from mildly elevated aminotransferase concentrations to fulminant hepatic failure.^{90,192} Eosinophilia and mononucleosis-type atypical lymphocytosis are common.¹³⁴ DRESS syndrome has been commonly mistaken for sepsis. Fatality rates are reportedly as high as 10%.¹⁸⁴

Skin biopsies reveal nonspecific perivascular lymphocytic infiltration, spongiotic or lichenoid dermatitis, and variable degrees of edema.¹⁹² Lymph node histology reveals benign hyperplasia, atypical lymphoid cells, or lymphoma. Other laboratory abnormalities include positive rheumatoid factor, antinuclear antibodies, antidouble-stranded DNA smooth muscle antibodies, cold agglutinins, and hypo- or hypergammaglobulinemia. A novel lymphocyte toxicity assay and serum thymus and activation-regulated chemokine (TARC) are being studied as potential diagnostic tests.^{126,130}

Prompt discontinuation of the offending antiepileptic is essential to prevent symptom progression. Patients should be admitted to the hospital and receive methylprednisolone 0.5 to 1 mg/kg/d divided in four doses.^{23,192} In one small case series, patients received high-dose methylprednisolone 7 mg/kg/d for 3 days followed by tapering doses of prednisolone for 30 days with associated good outcomes.¹²⁴ Other promising therapies include use of IV immunoglobulins.^{111,153,192} One patient was treated successfully with extracorporeal membrane oxygenation (ECMO) and intraaortic balloon pump after developing life-threatening myocarditis.¹⁰²

In one case series, 90% of patients with DRESS syndrome showed in vitro cross-reactivity to other aromatic antiepileptics.² Based on this evidence, avoidance of phenytoin, carbamazepine, phenobarbital, primidone, lamotrigine, levetiracetam, and oxcarbazepine is recommended; benzodiazepines, VPA, gabapentin, topiramate, and tiagabine are safe alternatives.

SUMMARY

- All antiepileptics produce CNS symptoms in overdose; therefore, differentiation based on clinical findings is difficult. Lethargy, sedation, ataxia, and nystagmus occur after overdoses of almost all the antiepileptics.
- Coma occurs after substantial overdose of all antiepileptics with perhaps the exception of gabapentin. Seizures are more common with tiagabine, lamotrigine, pregabalin, and carbamazepine overdoses.
- Hemodynamic instability and abnormal ECGs are rare findings. Carbamazepine, lamotrigine, and possibly topiramate can cause QRS complex prolongation.
- Except for VPA overdoses, there are no specific antidotes or overdoses of antiepileptics. Supportive care alone usually yields beneficial outcomes.
- Patients with severe VPA overdoses or VPA induced hyperammonemia should be treated with carnitine. Extracorporeal drug removal is rarely necessary and should be reserved for patients with severe carbamazepine toxicity.

A8 ANTIDOTES IN DEPTH

L-Carnitine

Mary Ann Howland

INTRODUCTION

L-Carnitine (levocarnitine) is an amino acid vital to mitochondrial utilization of fatty acids. It is approved by the US Food and Drug Administration (FDA) for treatment of L-carnitine deficiency that either results from inborn errors of metabolism or is associated with hemodialysis. L-Carnitine is also used off label to treat carnitine deficiency secondary to valproic acid toxicity or that associated with zidovudine (AZT)-induced mitochondrial myopathy^{10,11,19} and pediatric cardiomyopathy.¹⁷

Based on the proposed mechanism of action of valproic acid–induced hyperammonemia and valproic acid–induced hepatic toxicity, L-carnitine should theoretically help with both of these conditions, but the data to support this are limited. Based on the available evidence, L-carnitine should be considered for patients with valproic acid–induced hyperammonemia and valproic acid–induced hepatic toxicity. Symptomatic patients should receive L-carnitine intravenously; because of limited bioavailability, oral administration should be reserved for patients who are not acutely ill.

HISTORY

L-Carnitine is found in mammals, in many bacteria, and in very small amounts in most plants except for avocado and soy products.³⁶ Carnitine was first discovered in 1905 in extracts of muscle, and its name is derived from *carnis*, the Latin word for flesh.²⁰ Subsequently, its chemical formula and structure were identified, and in 1997, its enantiomeric properties were confirmed.³⁶ Carnitine was formerly known as vitamin BT.

PHARMACOLOGY

Chemistry

Carnitine is a water-soluble amino acid that can exist as either the D or L-form; however, the endogenous L isomer is the active form and should be used therapeutically. L-Carnitine (C₇H₁₅NO₃) has a molecular weight of 161 Da. At physiologic pH, L-carnitine contains both a positively charged quaternary nitrogen ion and a negatively charged carboxylic acid group.¹⁵

Mechanism of Action

Fatty acids provide 9 kcal/g and are important sources of human energy for the body, particularly for the liver, heart, and skeletal muscle. The utilization of fatty acids as an energy source requires L-carnitine–mediated passage through both the outer and inner mitochondrial membranes to reach the mitochondrial matrix, where β-oxidation occurs (Figs. 48–2 and 13–9). Enzymes in the outer and inner mitochondrial membranes (carnitine palmitoyltransferase and carnitine acylcarnitine translocase) catalyze the synthesis, translocation, and regeneration of L-carnitine.³² Binding of L-carnitine to fatty acids occurs through esterification at the hydroxyl group on the chiral carbon.¹⁵ The L-carnitine regenerated in the mitochondrial

matrix can also translocate in the opposite direction, from the matrix and through the inner membrane back to the intermembrane space. Acyl-coenzyme A (CoA) is transported by carnitine from the cytosol to the mitochondria and undergoes β -oxidation in the mitochondrial matrix, generating acetyl-CoA, which then enters the citric acid cycle for the generation of adenosine triphosphate (ATP).

L-Carnitine Homeostasis

Approximately 54% to 87% of the body stores of L-carnitine is derived primarily from meat and dairy products in the diet; the remainder is endogenously synthesized from trimethyllysine.³⁶ This amino acid, found largely in skeletal muscle, is converted to trimethylammonibutanoate (γ -butyrobetaine) and then carried to the liver and kidney for hydroxylation to L-carnitine.²⁰ Synthesis of L-carnitine in the liver and kidney occurs at a rate of approximately 2 $\mu\text{mol/kg/d}$ and is regulated by the amount of diet-derived trimethyllysine.^{20,36} L-Carnitine is filtered by the kidneys, and tubular reabsorption maintains serum L-carnitine concentrations in the normal range, which is approximately 40 to 50 $\mu\text{mol/L}$.³⁷

Pharmacokinetics of Exogenous L-Carnitine

Carnitine pharmacokinetics is very complex and must take into consideration extensive interconversion between L-carnitine and acylcarnitine as well as multicompartmental nonlinear pharmacokinetic modeling.³⁷ The current understanding of L-carnitine pharmacokinetics is largely derived from three major studies.^{9,18,43} L-Carnitine is not bound to plasma proteins. Its volume of distribution (V_d) of the central compartment (V_c) is 0.15 L/kg, approximating extracellular fluid volume. Its V_d is 0.7 L/kg. Both vary depending on the compartment model analyzed. The α half-life is 0.6 to 0.7 hours, with a terminal elimination half-life of 10 to 23 hours, but may be 25% to 50% shorter. The kidneys rapidly eliminate L-carnitine, and as the dose increases, renal clearance increases, reflecting saturation of renal reuptake by organic cation/carnitine transporter.³⁷ Baseline serum concentrations for L-carnitine are 40 $\mu\text{mol/L}$ but increase to a peak concentration of 1000 $\mu\text{mol/L}$ after 2 g of L-carnitine are administered intravenously. Oral (PO) administration of 2 g produces peaks of only 15 to 70 $\mu\text{mol/L}$, demonstrating poor oral bioavailability. The time to peak concentrations after PO administration occurs at 2.5 to 7.0 hours, indicating slow uptake and release by intestinal mucosal cells. After a 2 g carnitine dose, PO absorption is rapidly saturated, and no further absorption occurs after administration of 6 g PO. After a radiolabeled dose, most L-carnitine is metabolized to trimethylamine N-oxide and butyrobetaine, with only approximately 4% to 8% remaining unchanged. The metabolites trimethylamine and trimethylamine N-oxide may accumulate after chronic high-dose PO therapy in patients with severely compromised kidney function.⁹ Fecal excretion of L-carnitine is less than 1% of the total dose. Carnitor (L-carnitine) tablets are bioequivalent to the Carnitor PO solution, with a bioavailability of approximately 15%. After 4 days of dosing at 1980 mg (6 \times 330-mg tablets) twice daily or 2 g twice daily of the PO solution, the maximum serum concentration was 80 $\mu\text{mol/L}$.

ROLE IN VALPROIC ACID AND HYPERAMMONEMIA

Valproic acid may cause hyperammonemia ($>80 \mu\text{g/dL}$ or $>35 \mu\text{mol/L}$) without predictability for symptoms or hepatic dysfunction. Hyperammonemia and hepatic toxicity may be associated either with therapeutic dosing or an acute overdose. Approximately 35% of patients receiving valproic acid demonstrate hyperammonemia, often with corresponding reduced serum L-carnitine concentrations.⁷ In the absence of hepatic dysfunction, the postulated mechanisms for hyperammonemia are unclear but may result from interference with hepatic synthesis of urea or a small increase in ammonia production by the kidney.^{27,44} Valproic acid induces both carnitine and acetyl-CoA deficiencies by combining with L-carnitine as valproylcarnitine and with acetyl-CoA as valproyl-CoA. Ultimately, β -oxidation of all fatty acids is reduced, resulting in decreased energy production. Valproylcarnitine formation may inhibit the renal reabsorption of L-carnitine.³¹

Valproic acid stimulates glutaminase, favoring glutamate uptake and ammonia release from the kidney. Reduced glutamate concentrations lead to impaired production of N-acetylglutamate (NAGA), a cofactor for carbamoyl phosphate synthetase I (CPS I), which is responsible for the synthesis of urea from ammonia in the liver (Fig. 48–2).

In humans taking valproic acid, L-carnitine supplementation reduces ammonia concentrations.^{1,3,5,7,25,34,39,45} The delay for normalization of ammonia concentrations is unknown, but a preliminary report suggests that improved ammonia elimination with L-carnitine (3–15 hours) compared with published controls (11–90 hours), although the difference was not statistically significant.^{41,42}

ROLE IN VALPROIC ACID AND HEPATOTOXICITY

Valproic acid therapy is commonly associated with a transient dose-related asymptomatic increase in liver enzyme concentrations and a rare symptomatic, life-threatening, idiosyncratic hepatotoxicity similar to Reye syndrome.⁴ Liver histology of the latter demonstrates microvesicular steatosis, similar to that described in both hypoglycin-induced Jamaican

vomiting sickness ([Chap. 121](#)) and Reye syndrome. This occurrence presumably results from L-carnitine and acetyl-CoA deficiency, which inhibits mitochondrial β -oxidation of valproic acid and other fatty acids, causing hepatocellular accumulation. One study compared valproic acid administration in mice bred to have decreased carnitine stores with normal mice and found that those with decreased carnitine stores developed microvesicular steatosis of the liver and demonstrated decreased mitochondrial oxidative capacity.²³

Rat studies demonstrate that toxic doses of valproic acid over 7 days cause microvesicular steatosis, mitochondrial swelling, hyperammonemia, and hypocarnitinemia.⁴⁰ When coadministered with L-carnitine, the mitochondrial swelling, hyperammonemia, and carnitine concentrations were similar to control rats, and the microvesicular steatosis was reduced.⁴⁰

The strongest evidence for the benefit of L-carnitine treatment in improving survival from valproic acid–induced hepatotoxicity comes from the retrospective analysis of patients identified by the International Registry for Adverse Reactions to valproic acid.⁶ When 50 patients with acute, symptomatic hepatic dysfunction who were not treated with L-carnitine were compared with 42 similar patients treated with L-carnitine, only 10% of the untreated patients survived, but 48% of the L-carnitine–treated patients survived.⁶ Early diagnosis of patients, prompt discontinuance of valproic acid, and administration of intravenous (IV) rather than PO L-carnitine resulted in the greatest survival rate.⁶ Most patients received 50 to 100 mg/kg/d of L-carnitine regardless of the route of administration.⁶

Acute valproic acid overdose rarely causes hepatotoxicity.⁴¹ However, if a patient were to develop hepatotoxicity after a valproic acid overdose, the general consensus is to administer L-carnitine.^{22,24,25,30,33,38} Because who will go on to develop hepatotoxicity after a valproic acid overdose cannot be predicted, many authors recommend administering prophylactic doses of L-carnitine to patients with severe overdoses, often defined by encephalopathy or a valproic acid concentration > 450 mg/L, with or without evidence of hepatotoxicity.^{25,33,38,41}

L-Carnitine Concentrations

In the serum, 80% of L-carnitine is free, and approximately 20% is acylated.¹⁴ In adults who eat all food groups and children older than 1 year of age, the normal serum concentrations of free L-carnitine are 22 to 66 $\mu\text{mol/L}$ and of total L-carnitine concentrations are 28 to 84 $\mu\text{mol/L}$. Vegetarians have L-carnitine concentrations 12% to 30% lower than omnivores.³⁵

Studies in patients taking valproic acid demonstrate decreases in both free and total serum L-carnitine concentrations³⁴ and decreases in both total and free muscle carnitine concentrations.²

Case studies demonstrate reduced serum free L-carnitine concentrations and abnormal valproic acid metabolite profiles that normalize with L-carnitine supplementation.^{21,28,29} All of these data support the therapeutic use of L-carnitine and provide a potential mechanism for its beneficial effects in valproic acid–induced hepatotoxicity.

ADVERSE EFFECTS AND SAFETY ISSUES

L-Carnitine administration is well tolerated.²⁶ Transient nausea and vomiting are the most common side effects reported, with diarrhea and a fishy body odor noted at higher doses.⁹ After chronic high doses of L-carnitine in patients with severely compromised kidney function, the potentially toxic L-carnitine metabolites trimethylamine and methylamine N-oxide accumulate. The importance of this accumulation is unknown. Trimethylamine and its metabolite dimethylamine may contribute to cognitive abnormalities and the fishy odor.¹³ In a pharmacokinetic study after IV administration of 6 g of L-carnitine over 10 minutes, two of six subjects complained of transient visual blurring; one subject also complained of headache and lightheadedness. The manufacturer of L-carnitine has received case reports of convulsive episodes after L-carnitine use by patients with and without preexisting seizure disorders. No reports of seizures related to L-carnitine use can be found in the human literature. The only data suggesting carnitine-related seizures are found in a rat model.¹⁶

There are no known contraindications to the use of L-carnitine. However, only the L isomer and not the racemic mixture should be used because the DL mixture may interfere with mitochondrial utilization of L-carnitine.

OVERDOSE OF L-Carnitine

No cases of toxicity from overdose have been reported, although large PO doses may cause diarrhea.⁹ The LD_{50} in rats is 5.4 g/kg IV and 19.2 g/kg PO.⁹

PREGNANCY AND LACTATION

L-Carnitine is considered FDA pregnancy category B. There is no information on excretion into breast milk.

DOSING AND ADMINISTRATION

The optimal dosing of L-carnitine for valproic acid–induced hyperammonemia or hepatotoxicity has not been established. Recommendations for IV L-carnitine administration to patients with acute metabolic disorders resulting from L-carnitine deficiency range from 50 to 500 mg/kg/d.^{9,12} A loading dose equal to the daily dose may be given initially followed by the daily dose divided into 4 hourly doses. The 500-mg/kg/d dose was intended for children⁸ and offers no maximum dose. After the loading dose, the author suggests a maximal daily dose of 6 g. The PO dosing of L-carnitine usually is 50 to 100 mg/kg/d up to 3 g/d and should be reserved for patients who are not acutely ill.

For patients with an acute overdose of valproic acid and without hepatic enzyme abnormalities or symptomatic hyperammonemia, L-carnitine administration can be considered prophylactic, and enteral doses of 100 mg/kg/day divided every 8 hours up to 3 g/d are appropriate. For patients with valproic acid–induced symptomatic hepatotoxicity or symptomatic hyperammonemia, IV L-carnitine should be administered. The author suggests a dose of 100 mg/kg IV up to 6 g administered over 30 minutes as a loading dose followed by 15 mg/kg every 6 hours administered over 10 to 30 minutes.

FORMULATION AND ACQUISITION

L-Carnitine is available as a sterile injection for IV use in 1 g/5 mL single-dose vials.⁹ L-Carnitine is supplied without a preservative. After the vial is opened, the unused portion should be discarded. L-Carnitine injection is compatible with and stable when mixed with 0.9% sodium chloride solution or lactated Ringer solution in concentrations as high as 8 mg/mL for as long as 24 hours.⁹ L-Carnitine is also available as 250 and 330 mg tablets; as a PO solution with artificial cherry flavoring, malic acid, sucrose syrup, and methylparaben and propylparaben as preservatives; and as a sugar free PO solution at a concentration of 100 mg/mL.⁸ The PO solution may be consumed without diluting, or it may be dissolved in other drinks to mask the taste. Slow consumption reduces gastrointestinal side effects.⁹

SUMMARY

- L-Carnitine should be administered to patients with valproic acid–induced hyperammonemia, hepatotoxicity, those with valproic acid concentrations above 450 mg/L and encephalopathy.
- Symptomatic patients should receive IV L-carnitine, not the oral preparation.

49 ANTIHISTAMINES AND DECONGESTANTS

Sophie Gosselin

Antihistamines and decongestants rank among the highest prescription and non prescription xenobiotics used in the United States. In 2011, antihistamines and cough and cold preparations ranked respectively 9th and 11th in substance categories most frequently involved in human exposures related calls to US Poison Control centers. Antihistamines ranked 11th place in categories associated with the largest number of fatalities in 2011 ([Chap. 136](#)).

Popular mythology suggests that expectorants or decongestants depress cough and relieve congestion, and antihistamines also promote sleep. In an effort to retain selected drugs on the nonprescription market, the US Food and Drug Administration (FDA) developed a nonprescription monograph rule allowing some medications in use before 1972 to remain on the market without new clinical trials. As such, many nonprescription decongestants, antihistamines, and expectorants remained available for children without adequate safety or efficacy data in younger age groups. Between the years 1998 and 2007, 8.7% of US parents surveyed reported to have used an antihistamine or decongestant containing remedy for their children younger than 12 years of age in the past week. The majority of these children were younger than 5 years of age. Pseudoephedrine, brompheniramine, and chlorpheniramine are the three most common ingredients used.¹⁷⁸

Unwanted effects associated with their use have posed significant public health problems particularly in children. Fatality studies associated with nonprescription cough and cold medicines reported that although uncommon, most deaths involved nontherapeutic dosages, administration for sedation purposes, and use in children primarily younger than 2 years of age.³⁴ However, the causality of death by cough and cold medicine is often debated. The data needed to prove this relationship are often incomplete because of such factors as the lack of postmortem drug quantification.¹³³ In 2007, a group of pediatricians and pharmacists petitioned the FDA requesting a change in labeling for children younger than 6 years of age on the basis that safety had never been demonstrated in this age group. This petition alerted the general public of the underestimated adverse effects of these xenobiotics.^{143,166} In early 2008, the FDA Public Health Advisory announced that cough and cold products were not recommended for children younger than 2 years of age, and later that same year the Consumer Healthcare Products Association (CHPA), a trade group of generic drug manufacturers, announced that its members were voluntarily modifying product labels for cough and cold medicines to exclude children younger than 4 years of age.¹⁷¹

Despite their widespread use, many reviews of nonprescription medications for cough in adults and children found no evidence for the effectiveness of these xenobiotics.¹⁵⁴ Conclusions are similar regarding the use of antihistamines or decongestants in otitis media.²⁸ Moreover, many well-conducted studies of antihistamines in monotherapy or in combination with a decongestant for patients with upper respiratory illness reported a significant absence of overall symptom improvement.^{154,176} It is also suggested that the majority of any perceived benefit of cough suppressants may be due to the sensory impact of sweetness and the placebo effect as well as the concerning intent of using the known adverse effect of sedation as a therapeutic goal.⁴⁵

A recent systematic review on the toxicity of common cough and cold remedies in children younger than 12 years of age concluded there is sufficient evidence of an unfavorable risk-to-benefit ratio to support measures aimed at restricting use of cough and cold medications in younger age groups.⁷³ As individuals seek to ameliorate the symptoms of an unpleasant illness, official restrictions in younger age groups have yielded concerns of increased off-label use of medicines intended for older age groups or substitution with other xenobiotics. Two recent analyses of both poison center data and emergency department (ED) visits reported significant decreases in annual rates of both therapeutic medication errors and overall ED visits related to cough and cold medicines. However, the rate of unintentional ingestions did not appear to have been modified after the marketing exposure changes in 2007, implying that further efforts to increase packaging safety and parental education are needed.^{88,101,147}

Despite many consumer-directed newsletter and media campaigns, it does not appear that overall use in the general population has decreased. This is indicated by the rising sales in the category “cough- and cold-related” nonprescription medications between 2008 and 2011, reaching \$4.2 billion in 2011, higher than analgesics (\$2.7 billion).²⁹ A survey done in 2010 for CHPA found that 93% of US adults prefer to treat their minor ailments with nonprescription products before seeking professional care, and 85% would do the same for their children.¹⁶⁰

Recreational use of antihistamines and decongestants as “legal highs” was reported as early as the 1970s.¹²⁴ The

popular “T’s and blues,” referring to the combination of pentazocine (Talwin) and the antihistamine tripeleennamine (blue-colored pills), were used intravenously as a substitute for heroin. In 1983, when naloxone was included in pentazocine (Talwin NX), abuse patterns decreased.¹⁰ Nonprescription sympathomimetics, such as pseudoephedrine, are also used as precursors in the synthesis of methamphetamine. Although the rates of potential adverse events are perceived as low, the issue takes on added significance when the magnitude of the exposure rates for these xenobiotics is considered. In a survey of 2528 participants distributed across the United States, 4.5% of adult participants in 2006 reported taking pseudoephedrine within the past week compared with 8.1% in 2002, and 3.8% reported the use of diphenhydramine compared with 4.4% in 2002.^{82,153} Both poison center and clinical experience suggests that recreational use of antihistamines may be increasing. Dextromethorphan-containing products are widely used for recreational purposes (Chap. 38).

Regardless of intent, exposures to these xenobiotics are relatively frequent, as illustrated by the number of calls received to the American Association of Poison Control Centers (AAPCC). Compilation of the National Poison Data System (NPDS) reports for the years 2001 to 2010 shows that although the total number of exposure calls related to antihistamines has increased in the last 10 years, reaching 3% of calls, the percentage of exposure per population covered by AAPCC remains constant at 0.03%. In contrast, both pediatric and adult cough and cold preparation-related calls have decreased since 2007 (Chap. 136).

In combination with each other, analgesics or antipyretics, antihistamines, and decongestants are easily accessible to the public. This availability perpetuates the widespread public impression that nonprescription xenobiotics are “safe” and contributes to their frequent use, misuse, and abuse.

ANTIHISTAMINES

History and Epidemiology

History. After the discovery of histamine, Daniel Bovet and other researchers at the Pasteur Institute attempted to synthesize antagonists to better understand its physiological role. In 1939, pyrilamine was found to be extremely effective in guinea pigs but not safe enough for humans. In 1941, phenbenzamine was the first antihistamine deemed suitable for clinical use.¹⁵⁶ Diphenhydramine was synthesized in 1943, and shortly after, in 1947, orphenadrine was derived. The more pronounced anticholinergic effects of the hydrochloride salt of orphenadrine explain its use in the treatment of Parkinson disease, and the citrate salt is used as muscle relaxant. In the same years, Searle and Company, in Chicago, modified diphenhydramine to reduce drowsiness. Dimenhydrinate, the resulting 8-chlorotheophylline salt, serendipitously cured a patient of her long-standing motion sickness. This benefit was proven in a clinical trial in 1949, in which 25% of the troops crossing the Atlantic from New York who received a placebo experienced seasickness compared with only 4% of those receiving dimenhydrinate.¹⁵⁶

Reports of adverse effects and toxicity were soon published. The first report of a death associated with diphenhydramine occurred in 1948.¹⁴ However, in this patient, several other factors could have been contributory to her demise. Deaths were also reported with methapyrilene, but given its frequent co-ingestion with propoxyphene or scopolamine and the variable postmortem serum concentrations reported, attribution of causality was difficult.¹³⁴ In the 1950s, more pediatric overdose cases were reported, and the resemblance to atropine poisoning was noted. At the time, treatment consisted of phenobarbital, “pressure respirations”, and cooling with tepid water sponges.¹³¹

In the following decade, more than 5000 compounds were synthesized by more than 500 chemists and tried for human use. Daniel Bovet was awarded the Nobel Prize in Physiology or Medicine in 1957 for his work related to the synthesis of compounds blocking the effects of bodily substances such as histamine.¹⁶

Cyclizine, a piperazine rather than a dimethylamine, was developed in the 1960s. It proved to be long acting and was used during the first manned flight to the moon by the National Aeronautic and Space Administration to control space sickness. It is no longer approved for use in the United States, although its derivative, hydroxyzine, remains in use.¹⁵⁶ In the 1970s, terfenadine was synthesized as a tranquilizer, but it lacked central nervous system (CNS) penetration. However, its peripheral antihistaminic effects proved useful. In 1989, more than 773 reactions to terfenadine were reported ranging from long QT interval to convulsions in supratherapeutic ingestions.³⁵ In 1992, the FDA issued a warning for the risk of torsade de pointes with terfenadine when administered with CYP3A4 inhibitors. Fexofenadine, its active metabolite, was marketed instead.¹⁵⁶

None of the initial xenobiotics could antagonize histamine-induced gastric acid secretion, leading to the determination of the existence of more than one type of histamine receptors. The histamine receptor subtypes were identified as H₁ and H₂. H₂ receptors were noted to be located in the stomach. Attempts to identify H₂ receptor antagonists identified guanylhistamine, a partial agonist, and initiated the understanding of the histamine receptors physiology.¹⁵⁵

Cimetidine was synthesized in 1972, but its binding to the heme moiety of the cytochrome P450 with resultant inhibition caused medication interactions as well as altered mental status.¹⁷³ Ranitidine, a less polar molecule, did not enter the CNS

and did not interfere with the P450 cytochromes. It rapidly became one of the best-selling drugs and stayed so for many years.

Seeking to better understand the action of histamine in the CNS, animal studies in the early 1980s postulated the existence of another histamine receptor located presynaptically. The existence of a distinct H₃ receptor inhibiting the neuronal synthesis of histamine (autoreceptor) when stimulated was validated with the development of the selective agonist R- α -methylhistamine and antagonist thioperamide.⁶ A fourth histamine receptor has recently been identified. Its primary function seems to modulate inflammatory and immune responses as well as nociception.⁷⁰ The numerous functions of histamine and its receptors in the nervous system, immune system, and other organs are continually being appreciated. Trials are underway for the use of H₃ and H₄ histamine receptor antagonists in CNS cognitive disorder, obesity, and allergic rhinitis treatments.⁹⁸

Epidemiology. Antihistamines are now available worldwide, and many do not require a prescription. These medications find widespread application in the treatment of conditions such as anaphylaxis, benign positional vertigo, dystonic reactions, hyperemesis gravidarum, gastroesophageal reflux disease, stress gastritis, and other histamine-mediated disorders. They are also used for their ability to act on other receptors in the treatment of serotonin toxicity. Additionally, they are used for symptomatic relief of allergy symptoms as in allergic rhinitis, conjunctivitis, or urticaria and are included in many combination cough and cold preparations as discussed previously. First-generation antihistamines are widely available without prescription and are also marketed as sleep aids. These two factors may contribute to their common ingestion in suicide attempts.¹²⁶ Second- and third-generation H₁ antihistamines are less frequently implicated in suicide attempts. Although reporting is not comprehensive, according to 2011 NPDS data, about one in five antihistamine-related exposures called to poison centers are intentional. A 10-year review of the NPDS statistics shows that although the total number of antihistamine exposures increased steadily from 2001 to 2010, with a peak of adult exposures in 2007. During this time, percentage of exposures per population served by the AAPCC has remained relatively constant. More than 35% of antihistamine exposures are related to diphenhydramine (**Chap. 136**).

H₂ antihistamines have a better safety profile in therapeutic and overdose situations.¹¹¹ Even though many references cite the possibility of bradydysrhythmias, hypotension, and cardiac arrest with massive ingestions or intravenous (IV) administration of H₂ antihistamines, these reports are rare. The incidence of adverse cardiovascular events with H₂ antihistamines is largely unknown. In the largest published review assessing 881 cases of lone cimetidine exposures, most were in children from 12 to 36 months of age, and 76% were unintentional in nature. No fatalities were observed.⁹¹ A review of NPDS reports from 2001 to 2010 did not identify any fatalities from single-product ingestion of cimetidine or other H₂ antihistamines. Only a few case reports of fatalities associated with acute exposures to H₂ antihistamines in adults can be found, mainly in forensic literature with little clinical information.⁷⁸

Children may be at increased risk for antihistamine toxicity. Most of the reported deaths in this age group are with diphenhydramine, but this may well be a reflection of its ubiquity.^{104,114} Fatalities are also reported with other antihistamines, albeit often in combination with dextromethophan and pseudoephedrine, making it difficult to attribute the cause of death to the antihistamine alone.¹⁵ Liquid formulations attractive to children and topical preparations are available, resulting in unintentional ingestions when accessible. First-generation antihistamines are also administered for their sedative properties by parents and prescribed by pediatricians for various purposes, including promoting recovery of sick children or as a relief for working parents.^{2,119} However, the result of a randomized trial of diphenhydramine for this indication showed it was no more effective than placebo for nighttime awakenings or parental happiness.¹⁰⁹

Pharmacology

Histamine Receptor Physiology. H₁ receptors are located in the CNS, heart, vasculature, airways, sensory neurons, gastrointestinal (GI) smooth muscle, immune system, and adrenal medulla. Through H₁ receptors, histamine interacts with G proteins in the plasma membranes. Stimulation of H₁ receptors results in increased synthesis by phospholipases A₂ and C, inositol-1,4,5-triphosphate, and several diacylglycerols (DAGs) from phospholipids located in cell membranes. Inositol-1,4,5-triphosphate causes release of calcium, which then activates calcium-calmodulin-dependent myosin light-chain kinase, resulting in enhanced cross-bridging and smooth muscle contraction. The active and inactive forms of this receptor subtype are in equilibrium at baseline, and histamine shifts the equilibrium to the active conformation.¹⁴⁹

H₁ receptors are most commonly associated with mediation of inflammation. The other functions of histamine and the H₁ receptor include control of the sleep-wake cycle, cognition, memory, and endocrine homeostasis. H₁ receptor stimulation also causes vasodilation, increases vascular permeability, and increases bronchoconstriction. Cardiac histamine H₁ receptor stimulation increases atrioventricular nodal conduction time.³⁶

H₂ receptors are located in cells of the gastric mucosa, heart, lung, CNS, uterus, and immune cells. H₂ receptor stimulation is mediated by adenylyl cyclase activation of cyclic adenosine monophosphate (cAMP)-dependent protein kinase

in smooth muscle and in parietal cells of the stomach and results in increased gastric acidity through stimulation of the H^+ - K^+ -ATPase pump, causing release of H^+ into the gastric lumen. The action of histamine on the H_2 receptor increases sinus node automaticity, ventricular contraction force, and coronary flow as well as vascular permeability and mucus production in the airways.^{70,149}

H_3 receptors are found in neurons of the central and peripheral nervous systems, airways, and GI tract. The action of histamine on H_3 receptors of the CNS decreases further release of histamine, acetylcholine, dopamine, and serotonin. H_3 receptors partly act to prevent excessive bronchoconstriction and are implicated in control of neurogenic inflammation and proinflammatory activity.⁹⁸

H_4 receptors are located in leukocytes, bone marrow, spleen, lung, liver, colon, and hippocampus. The H_4 receptor plays a role in the differentiation of myeloblasts and promyelocytes and in eosinophil chemotaxis.⁹⁸

All four types of histamine receptors are heptahelical transmembrane molecules that transduce extracellular signals via G proteins to intracellular second-messenger systems.¹⁴⁹ Xenobiotics acting at each of the four histamine-modulated receptor sites have been identified. To date, no H_3 or H_4 antihistamines are available for commercial clinical use (Fig. 49–1).

FIGURE 49–1. Structure of histamine and selected H₁ receptor antihistamines.

Histamine Receptors: Inverse Agonists versus Antagonists. All known H₁ histamine antagonists function as inverse agonists and are not simply reversible competitive antagonists. Rather than preventing the binding of histamine to its receptor as in a classical competitive antagonist model, these xenobiotics stabilize the inactive form of the histamine receptor and shift the equilibrium to this inactive conformation¹⁴⁹ (Fig. 49–2).

FIGURE 49–2. Action of histamine and antihistamines on the H₁ receptor. Molecular basis of action of histamine and antihistamines. (A) The inactive state of the histamine H₁ receptor is in equilibrium with the active state. (B) The agonist, histamine, has preferential affinity for the active state, stabilizes the receptor in this conformation, and shifts the equilibrium toward the active state. (C) An H₁ antihistamine (inverse agonist) has preferential affinity for the inactive state, stabilizes the receptor in this conformation, and shifts the equilibrium toward the inactive state. GDP = guanosine diphosphate; GTP = guanosine triphosphate. (Reproduced with permission from Simons FE, Simons KJ: Histamine and H₁-antihistamine: celebrating a century of progress. *J Allergy Clin Immunol.* 2011;128:1139–1150. Copyright Elsevier.)

However, for consistency with the medical literature and the current terminology for these xenobiotics, the terms antihistamine or histamine antagonist rather than inverse agonist are used.

H₁ Antihistamines. Antiallergic and antiinflammatory activities of the H₁ antihistamines involve multiple mechanisms. Inhibition of the release of mediators from mast cells or basophils involves a direct inhibitory effect on calcium ion channels, thereby reducing the inward calcium current activated when intracellular stores of calcium are depleted. Inhibition of the expression of cell adhesion molecules and eosinophil chemotaxis involves downregulation of the H₁ receptor–activated nuclear factor (δ B), which binds to promoter or enhancer regions of genes that regulate the synthesis of

proinflammatory cytokines and adhesion proteins.¹⁴⁹

Another classification system of H₁ antihistamines stratifies them by sedating properties and ability to cross the blood–brain barrier and refers to them in terms of generations as they appeared into clinical use. Positron emission tomography (PET) is now the standard method used to assess H₁ receptor occupancy of antihistamines in the CNS.¹⁹⁰

First-generation H₁ antihistamines readily penetrate the blood–brain barrier and produce CNS effects, including sedation and performance impairment. Central effects of the first-generation H₁ antihistamines likely result from their high lipophilicity or lack of recognition by the P-glycoprotein efflux pump on the luminal surfaces of vascular endothelial cells in the CNS. First-generation H₁ antihistamines also bind to muscarinic, serotonin and to α -adrenergic receptors as well as ion cardiac channels. Their binding to the voltage sensitive Na⁺ channels produces use-dependent block because of their much higher affinity to the inactivated Na⁺ channels and their binding to the K⁺ channels (IK_r) alters repolarization (Chap. 16).^{25,149}

Six major classes of H₁ antihistamines are traditionally recognized based on molecular structure. The classes were initially populated by first-generation derivatives of ethylenediamine (mepyramine, tripeleminamine), ethanolamine (diphenhydramine, doxylamine, orphenadrine, dimenhydrinate), alkylamines (pheniramine, chlorpheniramine, brompheniramine), phenothiazines (promethazine), piperazines (hydroxyzine), and piperidines (azatadine). Many of the classic antihistamines are substituted ethylamine structures with a tertiary amino group linked by a two- or three-carbon chain with two aromatic groups. This structure differs from histamine by the absence of a primary amino group and the presence of a single aromatic moiety.

Some H₁ antihistamines have relatively unique properties that have led to special uses or marketing. Although dimenhydrinate, chlorpheniramine, cyproheptadine, promethazine, and pyrilamine have been studied for their local anesthetic properties mediated by sodium channel binding, diphenhydramine is the most used antihistamine for this purpose in dentistry since the 1960s.⁹² Concerns arose with tissue irritation and skin necrosis when diphenhydramine hydrochloride 5% was used. Even though the 1% solution produces erythema without necrosis, its use should be reserved for patients truly allergic to conventional local anesthetics.¹⁵² Diphenhydramine and doxylamine find frequent application in nonprescription sleeping medications because of their sedative effects. Diphenhydramine and dimenhydrinate have relatively strong antimuscarinic activity and are used for the management of motion sickness. Oxatamide, a sedating H₁ antihistamine, may possess mast cell stabilizing properties possibly mediated via calcium-channel blockade and is associated with dyskinesia. Cyproheptadine has 5-HT₂ antagonist properties and is used in the treatment of serotonin toxicity.

Second-generation H₁ antihistamines are peripherally selective and have a higher therapeutic index. Second-generation H₁ antihistamines do not penetrate the CNS well because of their hydrophilicity, their relatively high molecular weight, and recognition by the P-glycoprotein efflux pump on the luminal surfaces of vascular endothelial cells in the CNS.²⁵ Second-generation H₁ antihistamines include astemizole, azelastine, cetirizine, ebastine, ketotifen, levocabastine, loratadine, mizolastine, olopatadine, and terfenadine. They have lower binding affinities for the cholinergic, α -adrenergic, and β -adrenergic receptor sites than do the first-generation antihistamines. Many are prodrugs that need to be converted in the liver to hydrosoluble metabolites.

Although not officially accepted terminology, metabolites or active enantiomers of second-generation H₁ antihistamines such as desloratadine, levocetirizine, and fexofenadine are sometimes referred to as third-generation antihistamines. They have fewer adverse drug reactions, but no study has confirmed their therapeutic advantages over the parent compounds. Fexofenadine, however, does not have the cardiac toxicity of its parent drug terfenadine. In a test of wheal suppression, which correlates better to receptor occupancy than plasma concentrations, fexofenadine had the earliest onset of action, and levocetirizine showed maximal inhibition at 3 and 6 hours.^{37,58}

Cautious prescribing practice may lead to a preference for second-generation H₁ antihistamines in patients whose activities are safety critical and may be affected by any psychomotor impairment (eg, those who operate motor vehicles).^{63,103} In a randomized placebo-controlled driving simulator trial, 60 mg of fexofenadine did not interfere with driving performance. However, 50 mg of diphenhydramine produced poorer driving performance than ethanol (100 mg/dL). Of note, subjective feelings of drowsiness were not predictors of impairment.¹⁸³ Despite these findings, care must be exercised in the selection and use of second-generation H₁ antihistamines because some subjective or objective sedation may still result from their use, especially if higher-than-recommended dosages are taken, particularly with cetirizine.^{38,137} Furthermore, a meta-analysis suggested that the differentiation between sedating and nonsedating H₁ antihistamines may be blurry, with some studies lacking the methodology to correctly distinguish between medication adverse effects and the signs and symptoms of the condition being treated.^{12,163} Overall, it appears that the relative incidence of anticholinergic and CNS adverse effects caused by second-generation H₁ antihistamines may be similar to that produced by placebo.³⁸ Using recommended doses of antihistamines, PET scanning shows that first-generation antihistamines occupy more than 70% of

the H₁ receptors in the frontal cortex, temporal cortex, hippocampus, and pons. In contrast, the second-generation antihistamines occupy less than 20% to 30% of the available CNS H₁ receptors.^{162,163}

H₂ Antihistamines. These structural analogs of histamine are highly selective inhibitors of the H₂ receptor site. Cimetidine is the original antihistamine in this class; it includes the imidazole ring of histamine (Fig. 49–3). Although ranitidine and famotidine have a furan (ranitidine) or thiazole (famotidine) group instead, they retain significant structural similarity to histamine.

FIGURE 49–3. Structures of H₂ receptor antagonists.

The effectiveness of H₂ antihistamines in the treatment of diseases caused by excessive gastric acid secretion is improved further by their concomitant alteration in the response of parietal cells to acetylcholine and gastrin, two other stimulants for gastric acid secretion (Fig. 49–4). Of note, H₂ antihistamines have little pharmacologic effect elsewhere in the body, and they have weak CNS penetration secondary to their hydrophilic properties.

FIGURE 49–4. Schematic representation of a gastric parietal cell demonstrating the mechanism of hydrogen ion secretion into the lumen. Gastric acid is modulated by both the calcium-dependent and cyclic adenosine monophosphate (cAMP)–dependent pathway. Histamine binding to the H_2 receptor increases gastric acidity by increasing cAMP. Both acetylcholine and gastrin increase gastric acidity by increasing the influx of calcium. Whereas acetylcholine binds at the muscarinic 3 (M_3) receptor, gastrin binds the cholecystokinin B (CCK_B) receptor.

H_3 Antihistamines. These xenobiotics are the focus of much research; however, none are currently commercially available.¹⁹² Some prototypical drugs include ciproxifan, clobenpropit, pitolisant, and thioperamide. This category is further divided into the imidazole-based and non-imidazole-based series.¹⁷² Because of nootropic (cognitive enhancement) and stimulant effects, it has been suggested that H_3 antihistamines might play a future role in the treatment of attention deficit and hyperactivity disorder, narcolepsy, depression, or dementia. Pitolisant has been granted orphan drug status in the European Union and United States. Its benefit in the treatment of narcolepsy is contested, and it is currently in clinical trials for Parkinson disease and schizophrenia.¹⁴² Conessine, a herbal used in Ayurvedic medicine for dysentery, is also a selective H_3 antihistamine.^{55,138}

H_4 Antihistamines. No commercially available xenobiotics of this class are currently available. Because of their association with mast cells and eosinophils, H_4 antagonists clinical trials are studying their potential therapeutic benefit in the treatment of allergic rhinitis, asthma, and autoimmune disorders.¹⁴⁹

Atypical Antihistamines

Other xenobiotics have been named atypical antihistamines because of their inhibitory effect on the enzyme histidine decarboxylase, which catalyzes the transformation of histidine to histamine as opposed to action on the H_1 receptor.

Tritoqualine has been commercially available in Europe since the 1960s and is used for persistent allergic rhinitis.¹²⁵ To date, no case report of overdose with atypical antihistamines has been published.

Pharmacokinetics and Toxicokinetics

H₁ Antihistamines

Absorption. H₁ antihistamines are generally well absorbed after oral administration, and most achieve peak plasma concentrations within 2 to 3 hours. Although less well studied, dermal absorption appears to be consequential, especially with extensive or prolonged application to abnormal skin.¹⁶⁷ The maximum antihistaminic effect occurs several hours after peak serum concentrations. In supratherapeutic or overdose circumstances, absorption can be prolonged by the antimuscarinic effect on the GI tract.

Although ingestion is the usual route of exposure, rare cases of topical preparations containing diphenhydramine and promethazine cause agitation attributed to anticholinergic toxicity in children. Blood concentrations in these patients may be above the peak therapeutic concentration of 0.06 mg/L.^{50,72,141,146,188} Many cases were with concomitant varicella infection, blurring the causality of the clinical findings attributed to topical diphenhydramine alone. Lumbar punctures were not done to exclude encephalitis, but symptoms improved with cessation of diphenhydramine. Several cases occurred after a bath, calling into question the role of peripheral vasodilation in increasing dermal absorption. Some patients had concomitant oral diphenhydramine therapy but none exceeding the recommended dose of 5 mg/kg/day. One death solely after exposure to topical diphenhydramine is reported in a child with eczema.¹⁶⁷ All cases of topical antihistamine-induced toxicity involved administration over significant body surface area on abnormal skin.

Distribution. Antihistamines are typically lipid soluble with variable octanol/water partition coefficients. They are also highly bound to plasma protein in therapeutic concentrations. The saturability of protein binding in toxic concentrations is largely unknown. The average volume of distribution is between 0.5 and 12 L/kg but can extend to 30 L/kg with desloratadine.

Metabolism. Hepatic metabolism is the primary route of metabolism for antihistamines.¹²¹ Cetirizine, fexofenadine, and levocetirizine are exceptions. A poor metabolizer phenotype of desloratadine has been identified in children and adults. In these individuals, the apparent half-life of desloratadine is 50 hours or more compared with the average population whose half-life is around 26 hours.¹²⁸ This variability has not been shown to impact the safety profile of desloratadine. Many Asian patients can acetylate therapeutic concentrations of diphenhydramine to a nontoxic metabolite twice as rapidly as white patients, making Asians much less sensitive to both the psychomotor and sedative effects.¹⁵⁸ Results of a study of 100 patients in a sample of 2074 antihistamine users reporting excessive daytime sleepiness after use of H₁ antihistamines (predominantly chlorpheniramine) suggest that the presence of the CYP2D6*10 allele is a risk factor for development of H₁ antihistamine-induced adverse drug reactions.¹³⁹

Excretion. Unchanged antihistamines and metabolites are renally excreted. Chlorpheniramine urinary excretion is increased in acidic urine. Elderly adults (mean age, 69 years) had similar time to peak concentrations but longer elimination half-lives of diphenhydramine compared with young adults.¹⁵¹

Elimination half-life is quite varied for all H₁ antihistamines with chlorpheniramine, hydroxyzine, azelastine, and levocabastine exhibiting the longest termination half-lives up to 24 hours.¹⁴⁹

The duration of action ranges from 3 hours to 24 hours, which is much longer than predicted from the serum elimination half-lives of the antihistamines. One study addressing the pharmacokinetics of diphenhydramine found that children (mean age, 8.9 years) reached peak plasma concentrations faster and had a shorter mean elimination half-life than young adults for the same dosage per kilogram.¹⁴⁹ Similar findings were observed with hydroxyzine.¹⁵⁰ In another volunteer study, desloratadine doses of 1 and 1.25 mg in children between the ages of 6 months and 2 years were found to provide a single dose target exposure (area under the plasma concentration–time curve) comparable with that experienced by adults receiving the recommended 5-mg dose.⁵⁷

Modifications in therapeutic doses may be required for patients with hepatic or renal dysfunction, young people, and elderly adults. Such modifications often must be made empirically because formal studies and recommendations for many xenobiotics are lacking. Patients with renal dysfunction might be more susceptible to developing toxicity from acute ingestion of a second-generation antihistamine, and dose adjustment is recommended for cetirizine, desloratadine, fexofenadine, levocetirizine, and loratadine.³³

Drug interactions. Recognized pharmacokinetic drug interactions involving the H₁ antihistamines are generally caused by modulation of CYP450 metabolism (most often CYP2D6 or CYP3A4) or via interference with active transport mechanisms such as P-glycoprotein or organic anion transporter polypeptide (OATP). The currently available second-generation H₁ antihistamines undergo fewer clinically relevant pharmacokinetic interactions than the first-generation H₁ antihistamines.^{9,40}

H₂ Antihistamines

Absorption. Cimetidine is rapidly and completely absorbed after oral administration, but only 40% to 50% of ranitidine and famotidine are bioavailable with a peak concentration within 3 hours. All have reduced absorption when administered concomitantly with food.

Distribution. Cimetidine has a volume of distribution of approximately 2 L/kg. Famotidine and ranitidine have a

variable volume of distribution in different age groups ranging from 1 to 4 L/kg. All have protein binding in the range of 15% to 25%.

Metabolism. Cimetidine has some hepatic metabolism (15%), but ranitidine and famotidine do not (<5%).

Excretion. Up to 70% of ranitidine is eliminated unchanged in the urine, and 10% is eliminated unchanged in the stool. Famotidine and cimetidine are also primarily renally excreted. Renal excretion is lower for oral than for IV administration.

Elimination half-life. The elimination half-life in patients with normal renal function is approximately 2 hours, but the half-life is substantially prolonged with impaired renal function (up to 10 hours) and in elderly adults (4 hours).

Interactions. Cimetidine is responsible for numerous drug–drug interactions because it can inhibit cytochrome P450 activity, thereby impairing hepatic drug metabolism. It can reduce hepatic blood flow, resulting in decreased clearance of drugs that are highly extracted by the liver. None of the other currently available H₂ antihistamines inhibit the cytochrome P450 oxidase system.¹⁰⁵ Additionally, by altering gastric pH, cimetidine and all of the other H₂ antagonists may alter the absorption of acid-labile xenobiotics. Finally, cimetidine and ranitidine are associated with myelosuppression, particularly when administered with xenobiotics capable of causing bone marrow suppression.⁷

Cimetidine is an inhibitor of ethanol-oxidizing activity of gastric alcohol dehydrogenase (ADH) in human isoenzymes, but inhibition by nizatidine and famotidine is negligible. It is likely a result of the thiazole group of these H₂ antihistamines preventing binding to the enzymatic substrate site.¹⁵⁹ In vitro data regarding ranitidine inhibition of gastric ADH yielded conflicting results. However, a human study comparing oral versus IV ethanol kinetics with ranitidine showed a significant reduction in first-pass metabolism.^{19,64} The first-pass metabolism of ethanol is influenced by the gastric mucosa, but it is unclear by which mechanisms ranitidine might influence increases in blood ethanol concentrations.¹¹⁷ The literature on the clinical relevance of these effects is conflicting.¹⁸ A meta-analysis of the effect of H₂ antihistamines on serum ethanol concentrations reported small elevations with cimetidine and ranitidine when administered concurrently, but the overall effect seemed unlikely to be clinically significant related to the accepted legal definitions of intoxication.¹⁸⁴ However, a later study reported raised ethanol concentrations in the range known to impair driving skills when ranitidine was taken regularly for 7 days before drinking.⁵ Asians are known to have increased gastric ADH as well as decreased ALDH-2.¹¹⁸ Combined therapy with H₁ and H₂ antihistamines were tried as a treatment for the “Asian flush” reaction with encouraging results. However, only H₂ antihistamines blocked the flushing reaction¹¹⁰ (Table 49–1).

TABLE 49–1. Pharmacokinetics Properties of Commonly Used Antihistamines in the United States

Antihistamine		Half-Life (hours) ^a	Duration of Action (h) ^a	Hepatic Metabolism	Log D ^c	Vd (L/kg) ^b	Urinary Elimination (%)
H₁ antihistamines							
First generation	Chlorpheniramine	12–43 (urine pH dependent)	24	Yes	1.13	5–7	30
	Cyproheptadine	N/A	4–6	Yes	4.93	N/A	72
	Diphenhydramine	3–14	12	Yes	1.92	3–4	4
	Doxylamine	10–11	N/A	Yes	1.15	2.7	N/A
	Hydroxyzine	13–27	24	Yes	2.21	13–31	15
	Promethazine	9–16	4–6	Yes	2.73	9–19	<1
Second generation	Cetirizine	6.5–10	12–24	<40%	–0.02	0.58	70
	Desloratadine	21–27	>24	Yes	2.95	10–30	41
	Fexofenadine	9–20	12–24	<8%	2.68	12	11
	Levocetirizine	N/A	>24	<15%	–0.83	0.41	85
	Loratadine	3–20	24	Yes	6.23	26–32	
H₂ antihistamines

Pathophysiology

The pathophysiology of acute H₁ antihistamine overdose is largely an extension of the expected therapeutic and adverse effects. These effects can be classified in broad categories according to the type of receptors involved. Acute H₂ antihistamine toxicity can be explained by a loss of selectivity for the gastric H₂ receptor and inhibition of the cardiac H₂ receptors responsible for positive chronotropy and inotropy.^{84,187}

The pathophysiology of H₁ antihistamine abuse is thought to be multifactorial. Humans are reported to abuse dimenhydrinate and diphenhydramine for their euphoric and hallucinogenic effects as well as for their reported anxiolytic and anticholinergic properties.⁶⁰ Recreational ingestion up to 5 g is reported, although most common recreational doses used to experience euphoria and hallucinations average 1 g.⁵⁹ Promethazine often combined with codeine, is widely abused in certain demographic groups.

However, animal studies of self-administration and conditioned place preferences suggest that antihistamines also have a rewarding potential independent of its euphoric effects, which increases with use. Dimenhydrinate abuse is linked to the stimulant effect of the 8-chlorotheophylline component but alone does not produce rewarding effects. However, diphenhydramine antagonizes muscarinic receptors, modulates serotonin function, enhances dopamine concentrations, and potentiate opioid receptors. It is now thought that the combination of diphenhydramine and the methylxanthine 8-chlorotheophylline as in dimenhydrinate has synergistic effect on the rewarding potential.⁵⁹ The dose–response for this to occur in humans remains to be studied. Older antihistamines such as chlorpheniramine are also selective serotonin receptor inhibitors, which might explain their nonmedical use⁶² (Table 49–2).

TABLE 49–2. Effects of H₁ Antihistamines

<i>Effects</i>	<i>Clinical Result</i>	<i>First Generation</i>	<i>Second Generation</i>
Must cell histamine inhibition	Decreased itching Decreased vascular permeability Vasodilation	Therapeutic	Therapeutic
Calcium ion channel blockage	Decreased mediator release	Therapeutic	Therapeutic
CNS H ₁ receptor occupancy	Sedation Impaired psychomotor performance	Marked effect in therapeutic and overdose	Minimal or no effect reported with cetirizine in overdose
CNS serotonin receptor antagonism	Increased appetite Weight gain	Occurs in therapeutic doses; no significance in overdose	No effect
Peripheral muscarinic receptor antagonism	Dry mucosa Decreased peristalsis Urinary retention Sinus tachycardia Mydriasis	Marked effect in overdose; minimal effect can occur at therapeutic doses	Minimal or no effect
Central muscarinic receptor antagonism	Agitation Delirium Hallucinations	Marked effect in overdose	No effect
α-Adrenergic receptors	Dizziness Hypotension	Marked effect in overdose; minimal effect can occur at therapeutic doses	No effect
Cardiac ion channel blockade	Prolonged QRS (I _{Na}) Prolonged QT interval (I _K)	Marked effect in overdose on Na ⁺ channel	Minimal or no effect at therapeutic doses except terfenadine, astemizole on K ⁺ channel

CNS = central nervous system.

Clinical Manifestations

H₁ Antihistamines. The toxic doses for each antihistamine are not well defined. The oft-cited threshold of toxicity of three to five times the therapeutic dose for first-generation antihistamines as well as cetirizine, loratadine, and fexofenadine originating from algorithms in various articles has never been validated.¹⁶⁴ Extrapolating plasma concentrations to an ingested dose is not accurate in predicting clinical effects for diphenhydramine and doxylamine.^{89,90} A dose-dependent relationship for diphenhydramine toxicity was published indicating a high risk of seizures with ingestions above 1.5 g in

adults.¹²⁹

Neurologic. Acute overdose of first-generation H₁ antihistamine usually results in the onset of toxicity within 2 hours. Dose–response effect accounts for the wide spectrum of altered mental status observed. Drowsiness seen in milder poisoning can rapidly progress to obtundation and seizures with larger ingestions. Compared with adults, children may more commonly present with excitation, irritability, or ataxia as well as being more prone to having hallucinations or seizures.⁸ Patients typically exhibit an anticholinergic syndrome, including mydriasis, tachycardia, hyperthermia, dry mucous membranes, urinary retention, diminished bowel sounds, and altered mental status such as disorientation and hallucinations. The skin may appear flushed, warm, and dry. Hyperthermia occurs in severe cases and correlates with the extent of agitation, ambient temperature and humidity, and length of time during which the patient cannot dissipate heat because of anticholinergic-mediated reduction in sweating ([Chap. 30](#)).

Some patients with high therapeutic dosing or after overdose develop a central anticholinergic syndrome in which CNS anticholinergic effects, such as hallucinations, outlast peripheral anticholinergic effects. At a later stage of ingestion the lack of tachycardia, skin changes, or other peripheral anticholinergic manifestations complicates establishment of the correct diagnosis for antihistamine poisoned patients unless there is a clear exposure history.^{56,182} Ingestion of second-generation H₁ and H₂ antihistamines usually does not result in significant CNS depression or anticholinergic effects except perhaps in pediatric patients or in adults with altered pharmacokinetic parameters. Although dry mouth and mydriasis are common adverse therapeutic effects, sedation is of the greatest concern.

Seizures can occur at any point in time in the course of the poisoning but typically begin in the first few hours and represent severe toxicity. Chlorpheniramine is both a serotonin reuptake inhibitor and a postsynaptic 5-HT_{1A} and 5-HT_{2A} receptor agonist.⁷⁹ Agonism of 5-HT receptors is associated with seizures. All first-generation H₁ antihistamines can produce seizures, although pheniramine seems to be more proconvulsant than others.²¹ Up to 22% of drug-induced seizures in children have been related to an antihistamine exposure, and diphenhydramine is a common cause of recreational drug-induced seizures.^{1,52,165}

Mydriasis develops at both therapeutic and toxic doses, with most patients describing blurred vision or diplopia. Both vertical and horizontal nystagmus may occur in patients with diphenhydramine overdose.⁴⁸

In a review of 136 patients with diphenhydramine overdose, somnolence, lethargy, or coma occurred in approximately 55% of patients, and 15% experienced a catatonic stupor.⁸⁹ Several reports suggest that young children experience more respiratory complications, CNS stimulation, anticholinergic effects, and seizures than do adults.¹¹⁴ In a placebo-controlled study comparing the CNS effects of the first- and second-generation H₁ antihistamines, the second-generation antihistamines caused less cognitive dysfunction and somnolence.^{38,69} This finding was corroborated in the simulated driving model in which loratadine produced significantly less impairment than diphenhydramine.⁶³ Use of diphenhydramine compared with loratadine in a work setting results in significantly higher injury rates.⁵¹ Observational postmarketing cohort studies conducted in England on large numbers of patients reported rates of sedation or drowsiness of fewer than 1% for desloratadine and levocetirizine.^{95,96}

Cardiovascular. Sinus tachycardia is a consistent finding after overdose with an H₁ antihistamine with anticholinergic effects and can persist after other toxic manifestations and delirium have resolved. Both hypotension and hypertension may occur.¹⁰⁰ These findings probably relate more to the patient's age, volume status, and vascular tone than to a specific class of antihistamines. Binding to inactivated channels results in prolongation of both the QRS complexes and QT intervals may occur with any first-generation H₁ antihistamine at doses that are supratherapeutic.^{27,92} Brugada-pattern electrocardiographic (ECG) changes are also reported.^{99,191}

Cardiotoxicity observed with terfenadine and astemizole may result from accumulation of the parent drug in cardiac tissue after inhibition of drug elimination (eg, terfenadine–ketoconazole interaction) and may be exacerbated by electrolyte (eg, Ca²⁺) imbalances or concomitant use of another ion channel blocker.^{13,68} They are no longer approved for use in the United States and many other countries. Second-generation H₁ antihistamines currently available are less dysrhythmogenic.^{65,127} Rare cases of QT interval prolongation have been reported in therapeutic situations, but the incidence of dysrhythmias with second-generation in overdose is unknown.³ One study reported six cases of patients taking amiodarone with loratadine who presented with episodes of torsade de pointes and syncope. Amiodarone accumulation has not been reported with co-treatment with loratadine, and all patients made a full recovery after loratadine was stopped. Loratadine accumulation via P450 CYP3A4 inhibition by amiodarone is the mechanism suspected to explain this occurrence.⁴ QT interval prolongation is reported with cetirizine (mainly with kidney failure or large ingestions), but none has been published with desloratadine or levocetirizine.³

Other. Rhabdomyolysis can occur in patients with extreme agitation or seizures after an H₁ antihistamine overdose.⁵³ Rhabdomyolysis is commonly noted in patients who overdose with doxylamine even in the absence of trauma or other common etiologies such as seizures, shock, or crush injuries. The mechanism remains undefined. A prospective study found

that 87% of patients who ingested more than 20 mg/kg of doxylamine developed rhabdomyolysis, and this dose was the best predictor of this complication.⁷⁵ Another retrospective review found a dose of more than 13 mg/kg to be the only predictive factor of doxylamine-induced rhabdomyolysis.⁸⁶ Rhabdomyolysis is reported as a rare adverse event after diphenhydramine overdose.⁴⁷ One case of compartment syndrome with diphenhydramine alone was published.¹⁷⁷ This complication more commonly occurs in association with other factors such as ethanol intoxication or immobilization. Creatine kinase concentrations are reported as high as 262,000 UI/L without seizure activity.^{42,47,85}

Unless complications such as aspiration or kidney failure develop, most patients are symptomatic for 24 to 48 hours with resolution of cardiac symptoms occurring before neurologic recovery. Anticholinergic delirium and residual sinus tachycardia can last a few days, but generally neither needs cardiac monitoring in intensive care settings. Other adverse effects mostly seen in therapeutic use include pancytopenia and cholestatic jaundice (cetirizine) fixed-drug rash, urticaria, photosensitivity, hyperthermia, transaminitis, or agranulocytosis. Hypersensitivity reaction to antihistamines is exceptionally rare but has been reported.³⁹ Postmortem findings are generally limited to pulmonary and visceral congestion, suggesting cardiogenic causes of death.⁸⁰

Special populations. Elderly patients are more susceptible to adverse events because kidney and liver dysfunction delay antihistamine metabolism.⁶⁹ All H₁ antihistamines cross the placenta, and some are teratogenic in animals. First- and second-generation agents fall into FDA categories B and C and should be individually addressed, avoiding or minimizing exposure when possible ([Chap. 31](#)). Because of their antimuscarinic effects, the first-generation antihistamines are generally contraindicated in patients with glaucoma or benign prostatic hypertrophy.

H₂ Antihistamines. These xenobiotics are well tolerated in overdose even after large ingestions. Patients may develop tachycardia, dilated and sluggishly reactive pupils, slurred speech, and confusion.^{157,173} In a retrospective study of acute cimetidine overdoses, 8.9% of patients had symptoms related to the ingestion, and those with reported moderate medical outcomes had ingested cimetidine with suicidal intent. Severe dysrhythmias, including ventricular fibrillation and bradycardia leading to fatal cardiac arrest in rapid IV infusion of cimetidine, are reported.¹⁴⁵ Deaths are reported in rare instances in large ingestion of cimetidine.⁸⁷

Famotidine and ranitidine produce even fewer dose-related toxicities in overdose. In addition, they are less likely than cimetidine to induce or inhibit the cytochrome P450 enzyme system, thereby producing fewer drug–drug interactions.⁷¹

Diagnostic Testing

The bedside diagnosis of antihistamine toxicity is a clinical one. Antihistamines cause false-positive results on several rapid urine drug screens by immunoassay to amphetamines (ranitidine), methadone (diphenhydramine, doxylamine), and phencyclidine (diphenhydramine, doxylamine). Cyproheptadine, diphenhydramine, and hydroxyzine have given false-positive results to tricyclic antidepressants (TCAs) in serum immunoassays only.¹⁶¹ Such results have caused concerns, particularly in children, and should always be confirmed if malicious intent is suspected.¹³⁵

Comprehensive blood or urine analysis screening with liquid chromatography/mass spectroscopy (LC/MS) or gas chromatography/mass spectroscopy (GC/MS) can provide antihistamine concentrations, but these are more useful in medicolegal or forensic situations. The turnaround time usually needed is unlikely to provide results at the time of initial assessment. Moreover, treatment is based on alleviation or correction of toxic signs or symptoms and should not depend on a concentration result that has not been shown to correlate with toxicity.^{85,89,90} Measurement of antihistamine concentrations in body fluids is not readily available and is generally unnecessary for clinical assessment and management.

Several publications have estimated the toxic diphenhydramine concentration in children to be around 5 mg/L. Fatal antihistamine concentrations are reported with great variability. However, as occurs in adults, toxic effects and fatalities are reported with lower concentrations. Considering diphenhydramine is subject to postmortem redistribution, it would be prudent to obtain blood samples as soon as possible to aid in determining the cause of death in fatalities involving these xenobiotics.⁸

Management

General Management. The initial management of a given exposure can begin by a consultation with a poison control center. Guidelines are published and validated with regards to the evidence-based out-of-hospital management of diphenhydramine and dimenhydrinate exposure allowing for home observation for any ingestion under 7.5 mg/kg in children younger than 6 years of age or under 300 mg or 7.5 mg/kg for adults and older children.^{11,140} Other criteria for medical evaluation for other antihistamines vary according to local practices, but in general, ingestions of less than five times the maximal therapeutic dose is rarely toxic.

Patients presenting to hospitals after exposure of any antihistamine must be triaged and medically assessed quickly, generally within 30 minutes of arrival, because those who will develop severe complications may be initially indistinguishable from those who will have a benign course, and the window for GI decontamination may soon elapse.

The individual should be attached to a cardiac monitor and observed for signs of sodium channel antagonism (increased QRS complex duration), potassium channel blockade (prolonged QT interval), and related dysrhythmias, as well as for seizures. IV access should be established and airway protection ensured.

Gastrointestinal decontamination can be undertaken with care to avoid aspiration in patients with large ingestions of first-generation H₁ antihistamines or early presentations but is generally not needed for H₂ antihistamines. The use of oral activated charcoal (AC), although more effective if administered early with regards to time of ingestion, can be considered even after a delay for ingestion of large amounts that might reduce absorption time. Multiple dose AC or whole-bowel irrigation (WBI) is usually not indicated. Neostigmine administration was used with success in drug-induced ileus, thus facilitating gut decontamination.²⁴

Enhanced elimination techniques do not benefit the toxicity of these xenobiotics because of their large volumes of distribution, extensive protein binding, and absence of enterobiliary circulation. However, exceptional case reports have been published using hemoperfusion and hemodialysis with resolution of the dysrhythmias previously unresponsive to treatment. These patients had ingested 20 mg/kg (adult) and 50 mg/kg (child) of diphenhydramine. All cases reported diphenhydramine concentrations in the fatal range. The mechanism proposed to explain these recoveries is that removal of diphenhydramine from the toxic compartment during extracorporeal treatment might have been enough to improve the distributive shock suspected to be from α -adrenergic blockade.^{106,113,179} Unfortunately, no clearance data, only blood concentrations before and after dialysis, have been reported, thus making conclusions on the efficacy of enhanced removal debatable and not recommended.

Assessment of the serum acetaminophen concentration is important because of its inclusion in many cough and cold products. Other laboratory studies should be obtained as indicated by history or physical signs and symptoms. Kidney function and creatine kinase should be obtained on all patients, particularly in patients with seizures or doxylamine overdose. Serum pregnancy tests should be obtained in women of childbearing age. An ECG should be obtained on all patients during the initial assessment and repeated at regular intervals, particularly if physostigmine use is considered.

The patient's vital signs and mental status must be monitored. Serial assessments of the patient's vital signs, particularly temperature, and mental status should be made. The potential for clinical deterioration necessitates management of symptomatic patients in a monitored environment.

Specific Treatments. **Sedation** can increase the risk for aspiration. Intubation to secure the airway is recommended when excessive sedation compromises ventilation.

Seizures should be treated with an IV benzodiazepine such as 2 to 4 mg (0.05–0.1 mg/kg in children) of lorazepam or 10 mg (0.2–0.5 mg/kg in children) of diazepam with repeated dosing as necessary.^{49,74} Hypertonic saline (3%) has also been shown to be effective in diphenhydramine-induced seizures in an animal model.⁶⁷ Recurrent seizures refractory to benzodiazepines or sodium bicarbonate should be treated with propofol or general anesthesia. Phenytoin use is discouraged as in most toxicologic-induced seizures.

Hypotension generally responds to isotonic fluids (0.9% sodium chloride solution or lactated Ringer solution). If the desired increase in blood pressure is not attained, sodium bicarbonate therapy or vasopressors can be titrated to achieve an acceptable blood pressure. In one instance, cardiogenic shock and myocardial depression resulting from a 10 g ingestion of pyrilamine could only be reversed with an intraaortic balloon counterpulsation device.⁵⁴ This approach should rarely be needed.

The sodium channel blocking (type IA antidysrhythmic) properties of diphenhydramine and other antihistamines may lead to wide-complex **dysrhythmias** that resemble those that occur after TCA overdose ([Chap. 71](#)). Hypertonic sodium bicarbonate reverses diphenhydramine or other antihistamine-associated conduction abnormalities^{27,49,74,144} (Antidotes in Depth: A5).

Type IA (quinidine, procainamide, disopyramide), IC (flecainide), and III (amiodarone, sotalol) antidysrhythmics are contraindicated because of their capacity to prolong the QRS and QT intervals. The use of IV lipid emulsion is reported with an ingestion of 1250 to 2500 mg of diphenhydramine. The common mechanism of action on sodium channels with TCAs and local anesthetics likely explains its success in restoring cardiac activity within minutes of administration after 60 minutes of unsuccessful resuscitation with 50 mEq of sodium bicarbonate, 2 mg of epinephrine, IV glucose, and 1 mg of atropine.⁷⁷

Rhabdomyolysis associated nephrotoxicity should be prevented by early use of IV fluid, NaCl 0.9%, to produce a urine output of 1 to 3 mL/kg/h. Once established, antihistamine-induced rhabdomyolysis is treated with IV fluids.¹²⁰ Although urinary alkalization may be helpful to prevent myoglobin-induced nephrotoxicity, its usefulness is controversial and might be best reserved when urinary pH is lower than 6.5.²⁶ Serum potassium and ECGs should be obtained to exclude significant hyperkalemia from muscle injury or acute kidney injury. Initial hypocalcemia caused by precipitation of phosphate from muscle breakdown should not be replaced unless dangerously low because calcium redistributes into the circulation in later phases.¹²⁰

Cooling via evaporative methods (tepid mist or cooling blanket or fan) is generally sufficient, but patients with severe

hyperthermia should receive more rapid cooling using an ice bath. **Hyperthermic** patients should be monitored for the development of disseminated intravascular coagulation and other complications. The goal is to return the patient to a normothermic state. There is insufficient evidence to recommend therapeutic hypothermia in poisoned patients with antihistamines.

Agitation or psychosis generally responds readily to titration of a benzodiazepine. Although most commonly a direct central effect, other frequent causes of agitation such as urinary retention or bright lights shone into dilated eyes unable to accommodate should not be forgotten. Physostigmine may effectively reverse the peripheral or central anticholinergic syndrome and can be used as a benzodiazepine-sparing strategy, but should only be considered after the initial cardiovascular toxicity, if present, has resolved or is no longer a possibility. It should be used with caution in an attempt to reverse coma or sedation caused by anticholinergic toxicity.

In a retrospective comparison of physostigmine and benzodiazepines, physostigmine was found to be safer and more effective for treating anticholinergic agitation and delirium.²² Contraindications to physostigmine use include wide QRS complex or bradycardia noted by ECG, asthma, and pulmonary disease. The primary benefits of physostigmine use in patients with antihistamine overdose include restoration of GI motility, elimination of agitation, and possible obviation of the need for computed tomography (CT) scan or lumbar puncture if the patient regains a normal mental status and can provide a clear history. The anticipated benefits of physostigmine must outweigh the potential risks before its use.

Before physostigmine is administered, the patient should be attached to a cardiac monitor, and secure IV access should be established. Physostigmine (1–2 mg in adults; 0.5 mg in children) should be administered by IV bolus over 5 to 10 minutes with continuous monitoring of vital signs, ECG, breath sounds, and oxygen saturation by pulse oximetry. The initial dose of physostigmine can be repeated at 5- to 10-minute intervals if anticholinergic symptoms are not reversed and cholinergic symptoms such as salivation, diaphoresis, bradycardia, lacrimation, urination, or defecation do not develop. When improvement occurs as a result of physostigmine, repeated doses of physostigmine at 30- to 60-minute intervals may be necessary, taking into account the fact metabolism of the offending xenobiotic is occurring and that subsequent doses might need to be lowered to avoid cholinergic symptoms. Another alternative for confirmed central anticholinergic symptoms expected to last many hours could be the administration of oral anticholinesterases such as donepezil, tacrine, or rivastigmine.^{37,116} They are noncompetitive reversible anticholinesterases, crossing the blood–brain barrier, with a longer duration of action than physostigmine. Continuous infusion of physostigmine has also been used successfully.¹²³ Benzodiazepines can be used, but excessive sedation with repetitive dosing can present undesirable effects. A dose of IV atropine should be available at the patient's bedside to treat cholinergic toxicity if it occurs (Antidotes in Depth: A9).

DECONGESTANTS

History and Epidemiology

History. Decongestants are xenobiotics acting on α -adrenergic receptors, producing vasoconstriction, decreasing edema of mucous membranes, and improving bronchiolar air movement. Ma Huang, the horsetail plant of the Red Emperor, was used in China for at least 2000 years before it was introduced into Western medicine in the late 19th century by Japanese researchers, who isolated the active ingredient from Ephedra plants. Ephedrine, the first xenobiotic of the sympathomimetic amine class to be used pharmaceutically, was first approved in 1926 by the Council of Pharmacy and Chemistry of the American Medical Association and was very popular in the treatment of asthma. Amphetamines were later synthesized to palliate to a shortage of Ephedra plant availability. Pseudoephedrine is a natural stereoisomer of ephedrine, and phenylephrine was introduced into clinical medicine in the 1930s and in 1949 replaced amphetamines in several compounds. Amphetamine was marketed as nasal decongestant (Benedrine Inhaler), which was eventually withdrawn in the 1960s because of widespread abuse.

Imidazoline decongestants, on the other hand, were derived from piperazine compounds while investigating their use as uric acid remedies to combat gout. As more imidazolines were synthesized for gout treatment, one of the compound, tolazoline, was found to have weak adrenergic blocking activity but its naphthyl analogue produced the reverse effect. Naphazoline was introduced in the 1940s as a decongestant. In the decades that followed, many imidazoline decongestants have been developed and tried for clinical use.¹⁵⁵

Epidemiology. Despite many years of widespread decongestant use in the United States and sporadic case reports of adverse effects, the magnitude and public health significance of adverse effects of this class of medications has only recently been appreciated. From 1991 to 2000, the FDA received 22 spontaneous reports of hemorrhagic stroke associated with phenylpropanolamine (PPA) use, and more than 30 other cases were reported in the literature since 1979. Statistical analysis published in 2000 confirmed that PPA is an independent risk factor for hemorrhagic stroke in women.^{23,83} The FDA recommended removal of PPA from the market in 2000 because of its association with intracranial hemorrhages. Many manufacturers took steps to remove or reformulate PPA-containing products well before the FDA rule-making process could be completed.

Fatality rates with decongestants suffer from the selection bias of case reporting as well as which xenobiotics are

examined. One study addressing the cause of death in children did not include imidazoline derivatives in their search strategy but these xenobiotics might have been included in part of the cases assessed.³⁴ Despite these biases, studies report a positive association between fatalities in children under 2 years of age and pseudoephedrine containing cough and cold medications resulting in high pseudoephedrine concentrations. Additional nonfatal adverse events also occurred in the children during that study period.³⁰

The majority of exposures are unintentional. NDPS data from 2011 report that only one in five cough and cold preparation exposures are intentional. In another study, postmortem analysis of unexpected infant fatalities yielded 10 deaths (ages 17 days–10 months) associated with the use of cough and cold medicines.¹³³ In response to new information and concerns, the FDA required labeling changes on medications aimed toward young children. In January 2012, the US Consumer Product Safety Commission proposed a new rule requiring child-resistant packaging for any nonprescription drug product containing the equivalent of 0.08 mg or more of an imidazoline in a single package.¹⁷⁰

Recreational use of ephedrine-containing stimulants is common, and combinations of these xenobiotics with caffeine or other herbs may be marketed as “herbal ecstasy” (Chap. 45). The sale of dietary supplements containing Ephedra, Ma Huang, *Sida cordifolia*, and pinellia (ephedrine alkaloids) was banned by the FDA in 2004 because of concerns over their cardiovascular effects, including hypertension, seizures, stroke, and dysrhythmias.⁵⁸ Companies challenged this rule in court, but it was finally upheld in 2006. Xenobiotics that contain chemically synthesized ephedrine, traditional Chinese herbal remedies, and herbal teas are not covered by the rule. Specific guidelines as to what constitutes a traditional remedy are still unclear and are currently under the FDA dietary supplement category.¹⁶⁹ Since then, many manufacturers have substituted ephedra by *Citrus aurantium*, whose principal ingredient is p-synephrine, and are marketing products as being “ephedra free.”¹³² The FDA ban on sales of ephedra had a significant reduction on the number of calls to poison centers and in the number of deaths.¹⁹³

Imidazoline abuse is also associated with strokes, although population incidences are not reported.⁹⁷ Of all the decongestants, only ephedrine and pseudoephedrine are on the list of xenobiotics monitored in competitive sports.¹⁸⁹ Phenylephrine and synephrine concentrations in urine are no longer monitored.

The Combat Methamphetamine Act signed into law in March 2006 limited methamphetamine precursor availability and additional precautions in pharmacies such as dispensing limits for nonprescription quantities, requesting personal identification, and storage of the medications behind pharmacy counters. This aimed to reduce potential harm associated with these xenobiotics by closing loopholes contained in the previous 2000 regulations.¹⁶⁸ The success of such stricter measures has yet to be quantified.^{107,115,135} Travel and Internet purchases being more common, it can also be expected that individuals might present with toxicity from xenobiotics not otherwise available in their countries of residence.

Pharmacology

Decongestants can be divided into two categories, sympathomimetic amines and imidazolines.

Sympathomimetics. The decongestants phenylephrine, pseudoephedrine, ephedrine, and PPA reduce nasal congestion by stimulating the α -adrenergic receptor sites on vascular smooth muscle⁷⁶ (Fig. 49–5). Both α_1 and α_2 receptor subtypes are linked to a Gq protein activating smooth muscle contraction via the IP₃ signal transduction pathway (Fig. 49–6). This process constricts dilated arterioles and reduces blood flow to engorged nasal vascular beds. The α -adrenergic mediated decrease in volume ultimately lowers resistance to airflow. Prolonged topical administration may produce rebound congestion upon discontinuation; possible mechanisms include desensitization of receptors and mucosal damage. This damage is caused by α_2 -adrenergic mediated arteriolar constriction resulting in decreased blood supply to the mucosa.

FIGURE 49–5. Structure of ephedrine and phenylpropanolamine decongestants.

FIGURE 49–6. Mechanism of action of the α -adrenergic decongestants. The α -adrenergic decongestants stimulate postsynaptic α_1 - and α_2 -adrenergic receptors to increase the concentration of inositol triphosphate (IP₃), which mediates vasoconstriction of blood vessels and reduces swollen mucosa. The imidazoline decongestants also bind to postsynaptic α_2 -adrenergic receptors on these blood vessels.

Phenylephrine is a direct α_1 -adrenergic receptor agonist with very little β -adrenergic agonist activity at therapeutic doses. Pseudoephedrine and ephedrine are mixed-acting direct and indirect nonspecific $\alpha_{1,2}$ -adrenergic and $\beta_{1,2}$ -adrenergic receptor agonists. Pseudoephedrine is the D-isomer of ephedrine and has only up to 25% of the adrenergic receptor activity of ephedrine.⁴³ PPA is an $\alpha_{1,2}$ -adrenergic receptor stimulant devoid of β -adrenergic receptor activity. PPA can directly stimulate $\alpha_{1,2}$ -adrenergic receptors and can indirectly stimulate these receptors by causing norepinephrine release.

Imidazolines. The decongestant effects of the imidazoline class of xenobiotics results from their vasoconstrictive action as α -adrenergic agonists, with binding to α_2 -adrenergic receptors on blood vessels. In addition, these medications show high affinity for imidazoline receptors, which are located in the ventrolateral medulla and some peripheral tissues. Three classes of imidazoline receptors are recognized. I₁ receptors mediate the inhibitory actions of imidazolines xenobiotics to lower blood pressure. I₂ receptor is an important binding site for monoamine oxidase, and I₃ receptor regulates insulin secretion from pancreatic cells.⁶¹ The imidazoline receptor field is in expansion as more physiological roles are found for these receptors, namely cell proliferation, regulation of body fat, inflammation, pain and opioid addiction, appetite, epilepsy, and neuroprotection. Table 49–3 summarizes the pharmacologic and toxic effect of available decongestants.

TABLE 49–3. Effects of Decongestants

	<i>Therapeutic</i>	<i>Duration Action (hours)</i>	<i>Toxic</i>
Imidazolines			
Naphazoline	Nasal decongestant	8	Acute: hypertension followed by hypotension, bradycardia, hypoventilation, hypotonia, CNS depression, hallucinations Chronic: mydriasis from ocular administration
Oxymetazoline	Otorrhea reduction	6–7	
Tetrahydrozoline	Nasal decongestant	4–8	
Xylometazoline	Nasal decongestant	5–6	
Sympathomimetic			
Ephedrine	Nasal decongestant	3–5	Hypertension, tachycardia, insomnia, psychosis
Phenylephrine	Nasal decongestant, vasopressor	1	Hypertension, reflex bradycardia
Pseudoephedrine	Nasal decongestant	3–4	Hypertension, tachycardia, insomnia, psychosis

The imidazoline (I) category of direct sympathomimetic receptor agonists is generally reserved for topical application. The agonists in this class are used for their local effects in the nasal passages and the eyes. The more common medications include oxymetazoline hydrochloride, tetrahydrozoline hydrochloride, and naphazoline hydrochloride (Fig. 49–7). The α_1 -adrenergic mediated vasoconstriction is complemented by an additive effect of preferential binding to α_2 -adrenergic receptors located on resistance vessels regulating blood flow. The imidazoline decongestants such as oxymetazoline and naphazoline are pure central and peripheral α_2 -adrenergic receptor agonists; tetrahydrozoline stimulates α_2 -adrenergic receptors and H_2 receptors. These medications are primarily used as nasal decongestants. Tetrahydrozoline is available without a prescription as an ophthalmic preparation to decrease conjunctival injection.

FIGURE 49–7. Structure of imidazoline and the imidazoline decongestants.

Selective α_2 -adrenergic receptor agonists acting on nasal veins for decongestant effect are being developed to minimize toxicity and adverse effects associated with current nonselective decongestants affecting nasal veins and arteries.³¹

Pharmacokinetics and Toxicokinetics

Sympathomimetics. Phenylephrine and other decongestants of this class are pharmacologically active after topical or oral administration. Absorption from the GI tract is rapid, with peak blood concentrations occurring within 2 to 4 hours of ingestion. They have variable hepatic metabolism via monoamine oxidase and mainly renal excretion. Children have shorter elimination half-lives of pseudoephedrine than adults at doses under 60 mg. Urinary elimination of pseudoephedrine is pH dependent.¹⁴⁸ Pseudoephedrine is excreted in breast milk, but use during lactation is considered acceptable.

Toxic effects can occur at therapeutic dosage in population with altered pharmacokinetics such as end-stage kidney disease. A meta-analysis found a dose–response relationship between blood pressure and pseudoephedrine in therapeutic situations.¹³⁶ Toxic symptoms are an extension of the adverse effects and follow a similar dose–response curve.

Imidazolines. The imidazolines are rapidly absorbed from the GI tract and mucous membranes. Despite their use for many decades, their metabolism has been poorly studied.¹⁰² Their elimination half-lives are from 2 to 4 hours. All imidazoline preparations have a relatively rapid onset of action, with 60% of maximum effectiveness occurring after only 20 minutes. Oxymetazoline is the only medication with duration of action more than 8 hours. The other preparations have an average duration of action of approximately 4 hours.

The toxicity of these medications follows a dose–response curve and accentuates the action on receptors. There is no information regarding modification of pharmacokinetics parameters in supratherapeutic conditions.

Pathophysiology

Sympathomimetic. Sympathomimetic decongestants cause their toxic effects via excessive stimulation of the adrenergic system and in effect produce signs and symptoms associated with the sympathomimetic toxidrome. Excessive vasoconstriction can result in end-organ damage to the brain, retina, heart, and kidneys.

Imidazolines. Imidazolines stimulate imidazoline receptors and produce a sympatholytic effect that in supratherapeutic conditions results in marked bradycardia and hypotension as well as a sympathomimetic syndrome.

Clinical Manifestations

Sympathomimetics. Ingestions of less than 1 mg/kg of pseudoephedrine in children have been reported to produce almost no toxicity and are generally managed conservatively without the need for hospital evaluation. A study of acute ingestions in children age 6 months to 5 years reported an absence of symptoms at doses lower than 120 mg and lethargy with doses above 360 mg.¹⁸⁶ After a decongestant overdose of this class, most patients present with a sympathomimetic syndrome with CNS stimulation, hypertension, tachycardia, or reflex bradycardia in response to pure α_1 -adrenergic agonist induced hypertension (**Chap. 76**). Approximately four to five times the recommended dose of pseudoephedrine may be required to cause hypertension.^{43,46} An increase in sinus dysrhythmias is reported in adults with ingestion of 120 mg of pseudoephedrine and moderate exercise.¹⁷ Headache was the most common initial symptom (39%) reported by patients who later developed severe toxicity from PPA. In 45 patients who developed hypertensive encephalopathy from PPA ingestion, 24 patients developed intracranial hemorrhages, 15 developed seizures, and six died.⁹³ Seizures, myocardial infarction, bradycardia, atrial and ventricular dysrhythmias, ischemic bowel infarction, and cerebral hemorrhages are

reported, even with therapeutic dosing.^{23,180} In a review of 500 reports of adverse reactions from patients who had ingested ephedrine and associated stimulants as dietary supplements, eight fatalities from myocardial infarction and cerebral hemorrhage were reported.¹²² Psychosis, agitation, and manic behavior have been reported with acute ingestion.

Imidazolines. When ingested, the imidazoline decongestants naphazoline, oxymetazoline, tetrahydrozoline, and xylometazoline are potent central and peripheral α_2 -adrenergic and imidazoline receptor agonists. In overdose, they can cause CNS depression, and initial brief hypertension followed by hypotension, bradycardia, and respiratory depression similar to clonidine (**Chap. 63**).⁶⁶ Children are particularly sensitive to the effects of the imidazoline decongestants. Cases of acute stroke have been reported in adults with naphazoline abuse.³²

Rare cases of cardiomyopathy with apical ballooning (Takotsubo) after large ingestion or chronic use of pseudoephedrine or oxymetazoline are reported.^{181,194} Acute respiratory distress syndrome from vasoconstriction of pulmonary vessels can also occur with both classes of decongestants. Reversible encephalopathy with bilateral posterior hemispheric edema on neuroimaging was reported after nonprescription use of pseudoephedrine albeit in a patient with an autoimmune disorder that might have been a predisposing factor.⁴⁴ Toxic effects usually resolve within 8 to 16 hours. However, they may persist for more than 24 hours if a sustained-release product is ingested.

Diagnostic Testing

The bedside diagnostic of decongestant toxicity is a clinical one. Sympathomimetic decongestants can cause false-positive results on several rapid urine drug screens by immunoassay to amphetamines.¹¹² Comprehensive blood or urine analysis screening test by LC/MS or GC/MS can be obtained for research purposes, in child abuse, or in forensic studies to determine the cause of death. They have no role in the immediate clinical management of poisoned patients.

Management

Patients presenting after an exposure to decongestants should be triaged promptly and brought to a monitored environment. A cardiac monitor should be attached to the patient and observed for dysrhythmias. IV access should be established and airway protection ensured. GI decontamination with AC should be done in large ingestions of pseudoephedrine if no contraindications are present. A retrospective study of xylometazoline ingestion in children reported toxicity above nasal or oral exposure exceeding 0.4 mg/kg body weight. Ingestions of more than 0.1 mg/kg of naphazoline or tetrahydrozoline produced severe toxicity in children. The decision to give AC in these instances should be made individually because liquid formulations are rapidly absorbed and might not be amenable to AC adsorption by the time of presentation.¹⁷⁴ AC administration may be beneficial several hours after ingestion of sustained-release decongestant preparations. More than one dose of AC may be considered to complete GI decontamination in massive ingestion of oral preparations, but multidose AC for enhanced elimination purposes has no role. WBI and renal-enhanced elimination techniques are not indicated.

Specific Treatment

Neurologic toxicity. Patients with extreme agitation, seizures, and psychosis should initially be treated with administration of oxygen and IV benzodiazepines, titrated upward to effect. A patient with a persisting headache, focal neurologic deficits, or abnormal neuropsychiatric examination findings after decongestant ingestion should be evaluated for cerebral hemorrhage by noncontrast head CT. If the timing of the imaging is delayed, reducing the sensitivity of this modality, subsequent lumbar puncture to exclude subarachnoid hemorrhage might be required.

Respiratory toxicity. Children presenting with respiratory depression from imidazoline decongestants have responded to naloxone. These case reports are too few to establish the efficacy of this therapy. Nevertheless, the use of naloxone in imidazoline toxicity seems to pose low risk in non-opioid-dependent patients. Many poison centers do recommend it.^{20,81}

Cardiovascular toxicity. Tachycardia, palpitations, and hypertension can occur in mild poisoning and usually respond to benzodiazepines. A patient who remains hypertensive or is believed to have chest pain of ischemic origin should be treated with phentolamine, an α -adrenergic antagonist, or nicardipine. Labetalol has been proposed and used in some reported cases; however, because of its different affinity for α - and β -adrenergic receptors depending on the route of administration, its use is not recommended when coronary vasospasm is suspected.¹⁷⁵ Labetalol is a more potent β - than α -adrenergic receptor blocker when given intravenously.^{94,108} β -Adrenergic antagonists should be avoided because of concern for unopposed α -adrenergic effects. An ECG is required, and any elevation of the ST segment warrants immediate consultation with a cardiologist.

Patients with ventricular dysrhythmias from sympathomimetic decongestants should be treated with standard doses of lidocaine or sodium bicarbonate. The evidence for efficacy of amiodarone in this setting is still lacking.^{41,130} PPA may cause hypertension with a reflex bradycardia and atrioventricular block that is responsive to standard doses of atropine. Atropine must be used with caution because it can cause a dangerous increase in blood pressure as the reflex bradycardia reverses. Therefore, a vasodilator such as phentolamine is preferred because the stimulus for the bradycardia is corrected with reversal of the hypertension.

Imidazoline-induced hypertension rarely requires therapy, but in the setting of symptomatic hypertension, a short-acting α -adrenergic antagonist such as phentolamine may be administered.¹⁸⁵ However, the hypertension is generally transient and

followed by hypotension. Initial antihypertensive therapy could exacerbate toxicity and should only be reserved for cases in which severe hypertension represents a true urgency for end-organ damage.

SUMMARY

- Anticholinergic toxicity is expected with H₁ antihistamines within a few hours of ingestion.
- Cardiotoxicity via sodium channel antagonism can be fatal and is treated with sodium bicarbonate.
- Physostigmine or other anticholinesterases can be used to reverse anticholinergic effects of H₁ antihistamines.
- H₂ antihistamines rarely result in symptoms or signs of toxicity.
- Decongestants used for recreational purposes can be ingested in doses producing toxic effects. The management is mainly supportive.
- Patients with abnormal mental status or seizures should be investigated to exclude intracranial hemorrhages.
- Topical imidazoline decongestants can produce toxicity.
- Sympathomimetic decongestants follow the same treatment guidelines as amphetamines and other agents of the sympathomimetic class.

A9 ANTIDOTES IN DEPTH

Physostigmine Salicylate

Mary Ann Howland

INTRODUCTION

Physostigmine is a carbamate that reversibly inhibits cholinesterases in the peripheral nervous system and central nervous system (CNS).⁴⁶ The tertiary amine structure of physostigmine permits CNS penetration and differentiates it from neostigmine and pyridostigmine, which are quaternary amines that have limited ability to enter the CNS. The inhibition of cholinesterases prevents the metabolism of acetylcholine, allowing acetylcholine to accumulate and antagonize the antimuscarinic effects of xenobiotics such as atropine, scopolamine, and diphenhydramine.⁵⁴ Although physostigmine previously was used as an antagonist to the antimuscarinic effects of cyclic antidepressants and phenothiazines, this use is no longer recommended because of a poor risk-to-benefit ratio, given the potential for exacerbation of life-threatening cardiotoxicity. Similarly, physostigmine has a poor risk-to-benefit ratio in the management of presumed γ -hydroxybutyric acid (GHB) toxicity.^{4,48,55} Atypical antipsychotics have complex pharmacologic effects. Although some atypical antipsychotics, such as olanzapine, have significant antimuscarinic side effects, the benefit of treating these anticholinergic effects with physostigmine must be weighed by the potential risks of exacerbating cardiotoxicity.^{19,47,53}

HISTORY

The history of physostigmine dates to antiquity and the Efik people of Old Calabar in Nigeria.^{17,21,24,46} The chiefs in this area used a poisonous concoction made from the beans of an aquatic leguminous perennial plant found in the area to create a judicial test the esere ordeal. Esere was the word used to represent both the bean and the ritual used to test the innocence or guilt of an accused person. They also believed that the esere had the power to detect and kill persons practicing witchcraft. Supposedly, innocent persons quickly swallowed the poison, which resulted in immediate emesis.²⁴ Vomiting allowed the innocent to survive without therapy or to be given an antidote of excrement in water. The guilty, however, hesitated swallowing, leading to speculation that sublingual absorption led to severe systemic symptoms without the benefit of vomiting. These persons were noted to develop mouth fasciculations and died foaming at the mouth. Daniell, a British medical officer stationed in Calabar, brought samples of the bean and the plant back to England in 1840.²⁴ John Balfour, a professor of medicine and botany at the Edinburgh Medical School, characterized the plant, which became known as *Physostigma venenosum* Balfour (family Leguminosae), in 1857. The active alkaloid was isolated by Jobst and Hesse in 1864 and was named physostigmine. Independently, one year later Vee and Leven also isolated and named the active alkaloid eserine.

Christison performed the first toxicologic studies, including self-experimentation with increasing doses of the seed. Fraser, Christison's student and successor, originated the concept of antagonism from his experiments with physostigmine and atropine. Fraser plotted the dose relationships between the effects of atropine versus physostigmine on various organs such as the eye and the heart, demonstrating the antidotal effects of atropine for the lethal effects of physostigmine.¹⁷ Subsequent experiments with physostigmine led to the development of the theory of neurohumoral transmission.²¹ By the 1930s, physostigmine was used as a miotic for patients with glaucoma, a treatment for myasthenia gravis, for reversal of the paralytic effects of curare, and an antidote for atropine and insecticides.

PHARMACOLOGY

Chemistry

Physostigmine salicylate is the salicylate salt of physostigmine, a carbamate with a molecular weight of 275 Da. **Figure A9-1** shows the general formula for carbamate cholinesterase inhibitors and the chemical structures of physostigmine ($C_{15}H_{21}O_2N_3$), a tertiary amine, and neostigmine, a quaternary amine.

A. General formula for carbamate inhibitors

B. Physostigmine

C. Neostigmine

FIGURE A9–1 (A) General formula for carbamate cholinesterase inhibitors. (B) Structure of physostigmine. (C) Structure of neostigmine.

Mechanism of Action

Physostigmine is a reversible acetylcholinesterase inhibitor. Similar to acetylcholine, physostigmine is a substrate for the cholinesterases (choline ester hydrolases), erythrocyte acetylcholinesterase, and plasma cholinesterase. Both acetylcholine and physostigmine bind to cholinesterases to form a complex, from which part of the complex known as the leaving group (ie, choline for acetylcholine) is removed, and the remaining acetylated (for acetylcholine) or carbamoylated (for physostigmine) enzyme is hydrolyzed, regenerating the enzyme and freeing the acetate or carbamate groups, respectively (Figs. 113–2 and 113–3). For acetylcholine, the process is extremely rapid, with a turnover time of 150 msec. In contrast, the half-life for hydrolysis of the carbamoylated enzyme is 15 to 30 minutes.⁴⁶ The I_{50} (molar concentration that inhibits 50% of the enzyme) of physostigmine is 2.3×10^{-7} M for acetylcholinesterase, which is much weaker than for other carbamates at 1×10^{-10} M and many organic phosphorus compounds at 1×10^{-11} M.²² Only the S-isomer of physostigmine inhibits cholinesterases, with plasma cholinesterase slightly more sensitive than acetylcholinesterase.³ Newer xenobiotics used in the treatment of Alzheimer disease¹¹ show selectivity for the CNS and for acetylcholinesterase. This group includes tacrine, donepezil, and galantamine, which are reversible cholinesterase inhibitors, and rivastigmine, considered a pseudoirreversible or slowly reversible inhibitor. These pharmaceuticals and neostigmine²³ have undergone limited study for reversal of anticholinergic poisoning.^{11,23,27,40}

Pharmacokinetics and Pharmacodynamics

Physostigmine is poorly absorbed orally, with a bioavailability of less than 5% to 12%.^{1,37} Cholinesterases rapidly cleave the ester linkage resulting in very little unaltered physostigmine elimination in the urine. Pharmacokinetic parameters after intravenous (IV) administration of 1.5 mg over 60 minutes in nine patients with Alzheimer disease demonstrated the following: volume of distribution, 2.4 ± 0.6 L/kg; half-life, 16.4 ± 3.2 minutes; peak serum concentration, 3 ± 0.5 ng/mL; and clearance, 0.1 L/min/kg (7.7 L/min). There was a threefold interindividual variability in plasma physostigmine concentrations. Plasma cholinesterase concentrations demonstrated inhibition within two minutes of initiating the

physostigmine infusion. The half-life of plasma cholinesterase inhibition was 83.7 ± 5.2 minutes, with full recovery within 3 hours of termination of physostigmine infusion. The effects on plasma cholinesterase inhibition lasted approximately five times longer than the half-life of physostigmine.²⁶ All patients experienced varying degrees of diaphoresis, nausea, vomiting, headache, and generalized fatigue despite pretreatment with 2.5 mg of methscopolamine.^{2,26}

ROLE IN ANTIMUSCARINIC TOXICITY

Physostigmine was first used as an antidote in 1864 to counteract severe atropine poisoning.³³ Today its role is primarily in the treatment of antimuscarinic poisoning. More than 600 xenobiotics respond to physostigmine.¹² Anticholinergics fall into the categories of antimuscarinic (atropine, scopolamine, propantheline, benztropine, trihexyphenidyl), neuromuscular blockers (curare), and ganglionic blockers (trimethaphan). Other xenobiotics (antihistamines, antipsychotics, and antidepressants) have antimuscarinic properties that are not their primary therapeutic actions and are often considered adverse drug effects.

The clinical use of physostigmine has varied over time.⁴² Owing to its ability to cause CNS arousal, physostigmine was used in the 1970s to reverse the CNS effects of a large number of antimuscarinics and used inappropriately to treat toxicity from nonantimuscarinics.^{18,31,32,34,38} The success with regard to antimuscarinics is directly related to the inhibition of cholinesterase. The effects of physostigmine on nonantimuscarinic xenobiotics such as the benzodiazepines, opioids,^{28,39,51} and GHB^{4,48} result from either the direct action of acetylcholine on the reticular activating system or interdependence of central neurotransmitters.³⁴ Few serious adverse effects are reported.⁵⁰ However, asystole followed administration of physostigmine in two patients with tricyclic antidepressant (TCA) overdose.³⁵ This occurrence led to the realization that toxicity from TCA is complex and consists of more than just antimuscarinic effects.³⁵ Cyclic antidepressant induced sodium channel blockade causes myocardial depression, QRS interval prolongation, and ventricular dysrhythmias. Physostigmine augments vagal effects, thus contributing to decreased cardiac output and cardiac conduction defects. An extensive review of the literature concluded that the safety of physostigmine use for seizures or cardiotoxicity in the setting of cyclic antidepressant toxicity was difficult to predict and thus not recommended.⁴⁵ A reevaluation must conclude that the risks of physostigmine use for xenobiotics that are not primarily antimuscarinic often outweigh any benefit.

This analysis is certainly true with regard to GHB ([Chap. 83](#)) as well.⁴⁸ GHB is often used with other xenobiotics, and its effects are highly variable.⁵⁵ Recovery from GHB typically occurs spontaneously within several hours (16 minutes to 6 hours).^{7,8,14,29,48,49} Three patients in whom a presumptive diagnosis of GHB toxicity was made were treated with physostigmine.⁷ The three patients had an improved mental status within 5 to 15 minutes. One of these patients relapsed and then fully awakened 40 minutes later. This patient was incontinent of feces, an adverse effect likely caused by the physostigmine.⁷ All three of the patients were arousable before physostigmine use. Although anesthetic study of GHB in the 1970s is the rationale for current use, it is illogical in the care of those who illicitly use GHB.²⁰

However, in cases of antimuscarinic overdose, physostigmine use clearly is beneficial. A study of 52 patients showed that whereas physostigmine controlled agitation and reversed delirium in 96% and 87% of patients, respectively,⁶ benzodiazepines controlled agitation in 24% of patients but were ineffective in reversing delirium. A shorter time to recovery after agitation was observed in those treated with physostigmine. No significant differences between these groups with regard to side effects or length of stay were noted.⁶

Indications for physostigmine use include the presence of peripheral or central antimuscarinic manifestations without evidence of significant QRS or QT prolongation. Peripheral manifestations include dry mucosa, dry skin, flushed face, mydriasis, hyperthermia, decreased bowel sounds, urinary retention, and tachycardia. Central manifestations include agitation, delirium, hallucinations, seizures, and coma.^{16,30} The peripheral and central findings usually occur simultaneously. In the early phases of overdose, peripheral manifestations typically precede central manifestations, although the central manifestations often are more remarkable.^{1,5,9,13,15,22,41,44} The central findings may persist longer than the peripheral findings, particularly when a patient is recovering from an overdose of an antimuscarinic xenobiotic.

ADVERSE EFFECTS AND SAFETY ISSUES

An excess of physostigmine results in accumulation of acetylcholine at peripheral muscarinic receptors, nicotinic receptors (skeletal muscle, autonomic ganglia, adrenal glands), and CNS sites.²⁵ Muscarinic effects produce stimulation of smooth muscle and glandular secretions in the respiratory, gastrointestinal, and genitourinary tracts, and inhibition of contraction of most vascular smooth musculature. Nicotinic effects are stimulatory at low doses and depressant at high doses. For example, acetylcholine excess at the neuromuscular junction produces fasciculations followed by weakness and paralysis. Its effect on the CNS results in anxiety, dizziness, tremors, confusion, ataxia, coma, and seizures.²⁵ Electroencephalograms demonstrate asynchronous discharges followed by higher voltage discharges and a pattern similar to tonic-clonic

seizures.²⁵ The cardiovascular effects are dose dependent and directly related to the presence of the diverse muscarinic and nicotinic effects.²⁵ In addition to its inhibition of cholinesterase, physostigmine has a direct action on the nicotinic acetylcholine receptor ionic channel.⁴³

Physostigmine toxicity results when physostigmine is used in the absence of antimuscarinic toxicity or when excess doses are administered with regard to the antimuscarinic xenobiotic exposure. Patients overdosed with physostigmine should be managed with intensive supportive care, including mechanical ventilation if needed; IV atropine⁵² titrated to reverse bronchial secretions; and, rarely, pralidoxime to reverse skeletal muscle effects.¹⁰

Contraindications to physostigmine use include reactive airway disease, peripheral vascular disease, intestinal or bladder obstruction, intraventricular conduction defects, and atrioventricular block and in patients receiving therapeutic doses of choline esters and succinylcholine.^{36,37} It is unclear why the package insert also lists diabetes as a contraindication.³⁶ Drug interactions with cholinergic agonists (eg, ophthalmic pilocarpine); depolarizing neuromuscular blockers; or other anticholinesterases such as carbamates, organic phosphorous compounds, and pyridostigmine are expected to be additive when taken concomitantly with physostigmine. The actions of xenobiotics metabolized by plasma cholinesterases such as cocaine, succinylcholine, or mivacurium are expected to be prolonged.

Physostigmine salicylate injection contains sodium metabisulfite.³⁶ Sulfites may cause life-threatening anaphylactoid reactions in susceptible individuals.

PREGNANCY AND LACTATION

Physostigmine is US Food and Drug Administration pregnancy category C. Little information is available regarding the effects of physostigmine in pregnancy. Transient muscular weakness occurred in 10% to 20% of neonates whose mothers received anticholinesterase treatment for myasthenia gravis.³⁷ Physostigmine should only be given when the benefit clearly outweighs the risk. Safety in lactation has not been established.

DOSING AND ADMINISTRATION

The dose of physostigmine is 1 to 2 mg in adults and 0.02 mg/kg (maximum, 0.5 mg) in children intravenously infused over at least 5 minutes. The onset of action usually is within minutes.²² The dose can be repeated after 10 to 15 minutes if an adequate response is not achieved and muscarinic effects are not noted. Rapid administration may cause bradycardia, hypersalivation leading to respiratory difficulty, and seizures. Although the half-life of physostigmine is approximately 16 minutes, its duration of action usually is much longer (often >1 hour) and is directly related to the duration of cholinesterase inhibition.² After reversal of anticholinergic symptoms, additional doses may be required if clinical relapse occurs. The effective dose depends on the ingested dose and duration of action of the antimuscarinic xenobiotic. Although a total of 4 mg in divided doses usually is sufficient in most clinical situations,¹⁶ significant interindividual variability exists. Atropine should be available at the bedside and titrated to effect should excessive cholinergic toxicity develop. A dose of atropine administered at half the physostigmine dose is recommended.

FORMULATION AND ACQUISITION

Physostigmine is available in 2-mL ampules containing 1 mg/mL of physostigmine salicylate. The vehicle contains sodium metabisulfite and benzyl alcohol.³⁶

SUMMARY

- Physostigmine is used extensively in the fields of anesthesiology, emergency medicine, and medical toxicology.
- The only evidence-based use of physostigmine is for the management of patients with an antimuscarinic syndrome, particularly those without cardiovascular compromise who have an agitated delirium and a normal QRS duration.
- In these patients, physostigmine has an excellent risk-to-benefit profile.

50 CHEMOTHERAPEUTICS OVERVIEW

Richard Y. Wang

Although overdoses of chemotherapeutics are infrequent, these events are of greater consequence than overdoses of many other xenobiotics because most chemotherapeutics have narrow therapeutic indices. This is evident from survey data from poison centers in the United States. From 1988 to 2010, the median annual number of people exposed to chemotherapeutics reported to US poison centers was about 1000. In the past 5 years, the number of annual exposures to these chemotherapeutics has steadily increased to slightly over 1500 (Chap. 136). These exposures represent about one per 1000 cases of exposures to pharmaceuticals, or one per 2000 cases of all exposures annually reported to US poison centers. Approximately two-thirds of the people exposed to chemotherapeutics in these reports were adults, one-fourth of the group was young children, and the remainder was adolescents. The annual trend for the proportion of exposures among adults and children appears to have remained at approximately 70% and 25%, respectively, from 2001 to 2010. Children and adolescents between the ages of 6 and 19 years accounted for approximately 7% of the population annually exposed, and this frequency did not change between these years. Although these differences among age groups can represent the incidence of cancer in these populations, further analysis is warranted to better define the reasons for these observations because they are not apparent.

Among single exposures to chemotherapeutics reported to US poison centers from 2006 to 2010, the annual percentage of unintentional exposures was slightly above 97%, and the annual percentage of exposures resulting in moderate or major severity in toxicity remained at approximately 6%. The mortality rate was about two per 1000 single exposures in this same period. These observations are consistent with a hospital-based survey and can be attributed to the increased toxicity of these chemotherapeutics.²⁴ The prevalence of the exposure to chemotherapeutics is expected to continue to increase because of the increased availability of oral formulations⁷⁶ and their expanding therapeutic indications.

MEDICATION ERRORS WITH CHEMOTHERAPEUTICS

The importance of understanding the occurrence of medication errors is to prevent future events of a similar nature. Fortunately, medical errors related to the use of chemotherapeutics occur infrequently. The reported medical error rate for the chemotherapeutics varies from 0.04% to 5.5% based on data from US medical centers,^{13,22,24,71} although the true prevalence of these events remains unknown. The rates reported by international medical centers are similar.^{25,41,43,44,53,66} These reported estimates vary by the clinical setting (hospital vs. outpatient) and the patient population (adults vs. children). The outpatient setting and the treatment of children present several unique challenges to the health care system, including increased volumes, decreased control measures, increased workload, and unique dosing schemes such as dose based on body surface area.^{24,69} In a satellite pharmacy setting, two of the potentially lethal overdoses of cisplatin were a result of errors in duration of administration (100 mg/m² for 3–4 consecutive days instead of for 1 day).¹⁹ Lack of health care provider familiarity with the chemotherapeutics and dosing errors are major causes of these events. Chemotherapeutics used frequently, recently added to the formulary, and used in complex protocols can contribute to these errors.⁵²

The factors contributing to the occurrence of medication errors with chemotherapeutics and the measures identified to prevent these events, such as centralization of services (medical oncology, pharmaceutical) and the use of standardized protocols, are similar to those for other pharmaceuticals, and they are discussed elsewhere (Chap. 140).^{6,8,66} The centralization of services can reduce chemotherapeutic errors by 25% and the institution of information technology (IT), such as electronic prescribing protocols, production, and bedside scanning of barcodes for proper identification, can reduce medication error by 10%,⁸ although drug labeling errors continue to occur.^{41,44} Additional strategies to reduce these errors include tracking and following up on errors and increased patient education and participation.⁶⁰ Many of these preventive efforts can also improve worker safety by reducing occupational exposures. As more chemotherapeutics become available and their indications broaden, unintentional exposures and unintended dosing regimens will likely increase in number and frequency. The adoption of safety standards for the administration can limit these errors.³¹

Aside from unintentional exposures, additional factors leading to increased toxicity associated with chemotherapeutics include age, sex, comorbidities, compromised host state such as ascites, and diminished kidney and liver functions. Diminished hepatic clearance caused by altered enzyme expression can be accounted for by age, sex, smoking status, and

the concurrent use of other xenobiotics. Differences in sex can contribute to varying pharmacokinetic parameters, including bioavailability, distribution, metabolism, and elimination. Women treated with 5-fluorouracil (5-FU) for colon cancer had a twofold higher frequency of drug-related toxicity than men.⁷³ The manifestations included leukopenia, diarrhea, and stomatitis. Although the basis for this difference in toxicity between sexes is not known, it may result from a decreased 5-FU clearance in women.⁷⁹ Dihydropyrimidine dehydrogenase (DPD) inactivates more than 80% of fluorouracil by metabolizing it to 5-fluorodihydrouracil, and low or absent activity of this enzyme can result in hematologic and gastrointestinal (GI) toxicity from treatment with 5-FU or its prodrug capecitabine.

At an individual level, genetic polymorphisms can contribute to differences in xenobiotic response with resultant toxicity by altering targets, transporters, and enzyme complexes. Such variations have been characterized for several enzymes that are involved in the metabolism of chemotherapeutics. Two examples of this type of toxicity include irinotecan used for the treatment of metastatic colon cancer and amonafide used for the investigational treatment of secondary acute myeloid leukemia. Irinotecan is a topoisomerase I inhibitor that works through its active metabolite, SN-38, which can cause diarrhea and neutropenia at elevated concentrations.⁷⁵ A genetic variant of uridine diphosphate glucuronosyltransferase (UGT1A1) containing the T7 allele glucuronidates SN-38 at a slower rate than other variants, which results in increased SN-38 concentrations and increased toxicity.^{3,30} Amonafide, which is a topoisomerase II inhibitor, and its active metabolite, N-acetyl amonafide is formed by N-acetyltransferase 2 (NAT2). Patients capable of “rapid acetylation” have a genetic variation of NAT2 and are more likely to develop myelotoxicity than are slow acetylators.⁵⁴ There are additional polymorphisms in metabolism associated with chemotherapeutics.²¹ however, further work is necessary to define their clinical significance. Because of the narrow therapeutic index of the chemotherapeutics, the significance of such findings demonstrates the benefit of individual drug monitoring and genetic screening for use to maximize the therapeutic efficacy while limiting host toxicity.

CLASSES OF CHEMOTHERAPEUTICS

Most chemotherapeutics can be grouped into one of five categories: alkylating agents, antimetabolites, antimitotics, antibiotics, and platinum-based complexes (Table 50–1). Some new chemotherapeutics target specific proteins located on the cell membrane, such as growth factor receptors, to inhibit the proliferation of tumor cells^{36,55} (Fig. 50–1). They can be categorized as monoclonal antibodies (MABs) and protein kinase inhibitors (NIBs) based on their therapeutic approach. The antimetabolites are grouped by the substrates with which they interfere. Methotrexate (MTX) is a folate antagonist. Other xenobiotics with similar mechanisms but lesser toxicity include trimethoprim and pyrimethamine. The antimitotics are plant alkaloids, and they exert toxic effects by interrupting microtubule assembly. Others are naturally derived and include the antibiotics and the enzyme L-asparaginase, which can be isolated from bacteria. The alkylating agents are more commonly used than other antineoplastics and cause covalent binding to nucleic acids, which inhibits DNA activity (replication and transcription) (Fig. 50–2). The more notable chemotherapeutics in this class, including those with similar activity, are the nitrogen mustards, nitrosoureas, and platinum-based complexes. The antimetabolites and the alkylating agents are cell-cycle active, meaning that they only affect cells undergoing cell division. Some xenobiotics are phase specific; that is, they affect the cell only at a period during cell division. The cell cycle consists of the S phase (DNA replication) and the M phase (mitosis). DNA regulation and chromosomal separation occur during mitosis. Vincristine is M-phase specific, and cytarabine is S-phase specific in their sites of action. Other antineoplastics inhibit topoisomerase, which is necessary for DNA replication because it allows for reversible DNA strand breaks.

TABLE 50–1. Classification of Chemotherapeutics, Their Adverse Effects and Antidotal Therapy

<i>Class</i>	<i>Chemotherapeutic</i>	<i>Adverse Effects</i>	<i>Overdose</i>	<i>Antidotes</i>
Alkylating agents	Busulphan	Hyperpigmentation, pulmonary fibrosis, hyperuricemia	Myelosuppression	
	Dacarbazine	Hypotension, hepatocellular toxicity, influenzalike syndrome		
	Nitrogen mustards Chlorambucil, cyclophosphamide, ifosfamide, mechlorethamine, melphalan	Hemorrhagic cystitis, encephalopathy, pulmonary fibrosis	Seizures, encephalopathy, myocardial necrosis, kidney injury, hyponatremia	MESNA; methylene blue
	Nitrosoureas Bendamustine, carmustine, lomustine, semustine, streptozocin	Pulmonary fibrosis, hepatocellular toxicity, kidney injury	Myelosuppression (delayed onset and prolonged duration)	
	Procarbazine	MAOI activity		
	Temozolomide		Myelosuppression	
Antibiotics	Anthracycline Daunorubicin, doxorubicin, epirubicin, idarubicin	Dilated cardiomyopathy	Dysrhythmias, cardiomyopathy, CHF, myelosuppression	Dexrazoxane
	Bleomycin	Pulmonary fibrosis		
	Dactinomycin	Hepatocellular toxicity		
	Mitomycin C	Hemolytic uremic syndrome		
	Mitoxantrone	Dilated cardiomyopathy	Cardiomyopathy, CHF	None
Antimetabolites	Methotrexate	Mucositis, nausea, diarrhea, hepatocellular toxicity	Mucositis, myelosuppression, kidney injury	Leucovorin (folinic acid); Glucarpidase (carboxypeptidase G2)
	Purine analogs Fludarabine Mercaptopurine	Encephalopathy, muscle weakness Hyperuricemia, pancreatitis, cholestasis	Myelosuppression, hepatocellular toxicity	
	Pentostatin Thioguanine	Hepatocellular toxicity Hyperuricemia		
	Pyrimidine analogs Cytarabine	Acute respiratory distress syndrome, neuropathy, cerebellar ataxia		
	Fluorouracil, capecitabine	Cardiogenic shock, cardiomyopathy, cerebellar ataxia, diarrhea, mucositis, myelosuppression, neuropathy	Mucositis, myelosuppression, myocardial ischemia, cardiac conduction disorders	Uridine triacetate
Antimitotics	Taxenes Docetaxel, paclitaxel	GI perforation, peripheral neuropathy, dysrhythmias		
	Vinca alkaloids Vinblastine, vincristine, vindesine	Peripheral neuropathy, hyponatremia (SIADH)	Encephalopathy, seizures, autonomic instability, paralytic ileus, myelosuppression	
Enzyme	L-Asparaginase	Hypersensitivity, pancreatitis, coagulopathy	No reports	None
Monoclonal antibodies	Many: gemtuzomab, trastuzumab	Hypersensitivity specific to the site of action and infection	No reports	None
Platinum-based complexes	Cisplatin, carboplatin, oxaliplatin	Kidney injury, peripheral neuropathy, hypomagnesemia, hypocalcemia, hyponatremia, ototoxicity, myelosuppression	Seizures, encephalopathy, ototoxicity, retinal toxicity, myelosuppression, peripheral neuropathy	Amifostine; thiosulfate

Protein kinase inhibitors	Many: Gefitinib, sorafenib, erlotinib	GI (nausea, diarrhea), acneiform rash (folliculitis), nail fragility, and xerosis (EGFR inhibitor), interstitial lung disease (erlotinib, gefitinib), hypertension (inhibitors of VEGF and PDGF), hypothyroidism (sunitinib), and infection	Nausea, vomiting, facial rash, edema	None
Topoisomerase inhibitors	Camptothecins Irinotecan Topotecan Epipodophyllotoxins Etoposide, teniposide	Neutropenia, mucositis, diarrhea, early onset cholinergic syndrome (irinotecan) CHF, hypotension	Myelosuppression	None

CHF = congestive heart failure; EGFR = epidermal growth factor receptor; GI = gastrointestinal; MAOI = monoamine oxidase inhibitor; MESNA = mercaptoethane sulfonate; PDGF = platelet-derived growth factor; SIADH = syndrome of inappropriate antidiuretic hormone secretion; VEGF = vascular endothelial growth factor.

FIGURE 50–1. Sites of action of selected targeted agents. Tyrosine kinases initiate signal transduction pathways and production of transcription factors that are responsible for cellular processes, including proliferation, survival, angiogenesis, and progression. Growth factors, such as endothelial growth factor (EGF) and vascular endothelial growth factor (VEGF), bind and activate transmembrane tyrosine kinases by causing receptor dimerization and phosphorylation (1). VEGF promotes endothelial cell mitogenesis and migration, which leads to vascular proliferation (2). Tyrosine kinases can be inhibited by monoclonal antibody (MAB) binding at the cell surface receptor site (3) or by kinase inhibitors at the adenosine triphosphate (ATP) binding site or substrate-binding site or by causing a change in the conformation of the enzyme (NIB) (4).

FIGURE 50–2. Selected classes of cell cycle phase-specific chemotherapeutics and their sites of action in the cell cycle. Arrows represent the progression of the cell cycle by phases. G₀ (resting), G₁ (gap 1), G₂ (gap 2), M (mitosis), and S (DNA synthesis).

Because the majority of the cases of chemotherapeutics overdoses involve MTX, vincristine, mitoxantrone (related to the anthracyclines),⁶⁴ nitrogen mustards, and cisplatin, the discussion in this section focuses on these xenobiotics (see [Chap. 36](#) for a discussion of the Vinca alkaloids).

MECHANISMS OF ACTION

The mechanisms responsible for the cytotoxic effects of the antineoplastics are the disruption of cellular replication and proliferation, which impairs DNA function by causing strand breaks, inhibiting strand relaxation, and serving as inhibitory analogs of essential cofactors and nitrogenous bases of nucleic acids. For example, alkylating agents form reactive intermediates that covalently bind to nitrogenous bases on the DNA structure, which leads to the formation of strand breaks and mispairings. Cross-linkages between strands can occur with the nitrogen mustards because they contain two reactive chloroethyl side chains. The planar anthracycline antibiotics can intercalate with DNA to alter replication and cause strand breaks through oxidative damage induced by a reactive semiquinone intermediate. DNA strand relaxation can be impaired by topoisomerase inhibitors, such as topotecan. Topotecan is derived from camptothecin, which is isolated from the tree *Camptotheca acuminata*. Single methyl transfer reactions and base pairings are essential activities during DNA synthesis that are affected by the antimetabolites, which include structural analogs to folate, pyrimidines, and purines.

Recent cancer therapy includes chemotherapeutics that limit cellular proliferation by inhibiting growth factor receptor activation and enhancing cell lysis by antibody-dependent cell-mediated cytotoxicity and complement-dependent cytotoxicity. MABs to tumor cell surface antigens, such as CD20, CD52, and CD33, and the C1q complement are used to direct host defense mechanisms or deliver chemotherapeutics to these sites. For example, gemtuzumab ozogamicin is an antibody conjugated to the antibiotic calicheamicin, and it is directed at CD33-positive leukemic blast cells. Other antibody conjugates include radioactive isotopes and diphtheria toxin. In addition to these antigens, MABs against tumor growth factor receptors are available.

Tumor growth factors promote cell progression, proliferation, and differentiation by angiogenesis. Their receptors located at the cell membrane are characterized for certain tumors, such as epidermal growth factor receptor (EGFR) (lung, kidney, and GI tumors) and human epidermal growth factor receptor 2 (HER2) (breast). Vascular endothelial growth factor receptor (VEGFR) and platelet-derived growth factor receptor (PDGFR) are active in angiogenesis. Inactivation of these receptors can be accomplished with therapeutic MABs and protein kinase inhibitors. MABs prevent the activation of these receptors by inhibiting substrate binding to the receptor located at the extracellular surface. Kinase inhibitors are considered to be small molecule therapeutics that impair the adenosine triphosphate (ATP) activation of growth factor receptors, tyrosine kinase inhibitors, and certain signal transduction proteins responsible for tumor cell division, such as serine/threonine kinase inhibitors. The disruption of the proliferation of keratinocytes and GI mucosa and epithelial cells at

these tissue sites can account for the anticipated toxic effects from the use of MABs and kinase inhibitors directed at EGFR. The therapeutic use of the protein kinase inhibitors of VEGFR and PDGFR, such as sunitib and sorafenib, is associated with hypertension, which can be caused by endothelial dysfunction and diminished microvascular regrowth.

These MABs are derivitized from human and chimeric (human and murine) sources, which contribute to the toxicity. Immunologic responses to the presence of foreign proteins include rigors, nausea, vomiting, and rashes. Some organ-specific effects of varying antibodies include bone marrow, skin (via EGFR), kidney (hypomagnesemia via EGFR), GI (via EGFR), and cardiac (via HER2, trastuzumab).

MANIFESTATIONS OF TOXICITY

The chemotherapeutics are known for their toxicity to cells with a high level of mitotic activity, such as malignant cells. This characteristic feature accounts for their common clinical manifestations of toxicity, including mucositis, alopecia, and bone marrow suppression. They can also cause protracted vomiting because of their ability to stimulate the chemoreceptor trigger zone in the medulla by vagal and sympathetic pathways either directly or indirectly through the GI tract. The likelihood for vomiting depends on the dose, the route of administration, and the type of antineoplastic. Although the onset of emesis typically occurs within 6 hours and lasts for 24 hours, late onset emesis can occur with cisplatin cyclophosphamide, carboplatin, and doxorubicin. The time of onset for the other manifestations is typically in the first week after treatment, with mucositis preceding leukopenia, which varies depending on the antineoplastic and is dose dependent. For example, the nadir and recovery for neutropenia are about 7 to 13 days and 21 to 24 days, respectively, but more prolonged delays to recovery occur for busulfan and carmustine given at higher doses. Anthracyclines and platinum-based complexes are likely to cause severe neutropenia, and MTX, 5-FU, bleomycin, and doxorubicin are likely to cause mucositis and severe salt and water depletion because of the amount of GI fluid loss from diarrhea and vomiting. Death usually results from overwhelming sepsis as enteric organisms traverse compromised GI epithelium, enter the bloodstream, and attack a host with neutropenia from bone marrow suppression. Some of the unique manifestations for certain chemotherapeutics involve the skin, heart, central and peripheral nervous systems, and kidneys.

Dermatologic manifestations caused by chemotherapeutics can be due to hypersensitivity reactions, extravasations (Special Considerations: SC4), or cytotoxicity from the use of tyrosine kinase inhibitors for the EGFR (eg, gefitinib, erlotinib).⁸¹ Patients commonly develop pruritus, xerosis, erythema, and folliculitis or an acneiform rash that can desquamate during therapy. These reactions develop within the first week of treatment and continue for several weeks. The folliculitis is a dose-dependent response and typically resolves within weeks after treatment. The dermal response appears to be more intense with MABs than with the kinase inhibitors for the EGFR. The other kinase inhibitors (ie, sunitinib, sorafenib) involved with growth factor receptors for angiogenesis (ie, VEGFR, PDGFR) are associated with a “hand–foot” skin reaction, which is a painful erythema and edema of the palm and sole that leads to desquamation.

The cardiovascular manifestations of toxicity depend on the antineoplastic, and the common ones include congestive heart failure (CHF), dysrhythmias, and hypertension. The anthracyclines, cyclophosphamide, 5-FU, and arsenic trioxide can cause cardiac toxicity (Table 50–2). Although the anthracyclines are known for their late-onset cardiomyopathy, they can also cause acute cardiac manifestations. Those occurring within 24 hours of therapy include dysrhythmias, ST segment and T wave changes on electrocardiogram (ECG), diminished left ventricular ejection fraction (LVEF) leading to CHF, pericarditis, myocarditis, and sudden death.^{9,61,62,69,80} Arsenic trioxide (As_2O_3) used for the treatment of acute promyelocytic leukemia can cause dose-dependent prolongation of the QT interval and ventricular tachydysrhythmias, including torsade de pointes, during the course of treatment.⁵ Inorganic arsenic inhibits the slow (I_{Ks}) and rapid (I_{Kr}) delayed rectifier K^+ channels of ventricular myocytes, which impairs the efflux of potassium ions during ventricular repolarization (Chaps. 16 and 89). These ECG changes tend to develop after several days of drug therapy, reverse upon discontinuation of the drug, and occur more frequently during intravenous (IV) than oral therapy because of the increased blood concentration of arsenic from the IV route of administration.⁶⁵ Patients at increased risk for cardiac conduction disorders during arsenic trioxide therapy include those with hypokalemia and hypomagnesemia, taking medications that prolong the QT interval, and with underlying cardiac conduction disorders. Myocardial ischemia leading to cardiogenic shock can occur from the high-dose infusion of 5-FU.⁷⁴ The metabolite fluoroacetate⁴ is purported to cause endothelial damage and result in vasospasm.²⁸ Normalization of ECG findings, including diminished QRS voltage and abnormal ventricular wall motion, are expected by 48 hours after the discontinuation of infusion therapy.¹⁵ Within a few days of exposure, cyclophosphamide can cause CHF, hemorrhagic pericarditis, tamponade, and death at high doses from therapy during bone marrow transplant or the overdose setting. The cardiomyopathy from anthracyclines involves biventricular failure, and its onset is variable, from months to years. Although this period is usually 1 to 4 months, it tends to be longer for the less toxic anthracycline analogs.^{26,32,66} Trastuzumab is associated with a slight increase incidence of CHF from diminished LVEF among patients previously treated with anthracyclines or with underlying heart disease.²⁷ A potential mechanism for the enhanced cardiac toxicity from the drug interaction is that trastuzumab disrupts the HER2-neuregulin compensatory response by the heart to the exposure to anthracyclines.¹⁶ Lapatinib is another antineoplastic targeting HER2,

but by inhibiting phosphorylation at the tyrosine kinase domain, and it can lead to a slight decrease in LVEF.⁵⁰

TABLE 50–2. Cardiovascular Manifestations of Toxicity of Selected Chemotherapeutics

<i>Chemotherapeutic</i>	<i>Time of Onset since Treatment</i>	<i>Manifestation</i>
Anthracycline	<24 hours	Dysrhythmias, ST-segment and T-wave changes on ECG; diminished LVEF leading to CHF, pericarditis, myocarditis, and sudden death
	Months to years, typically at 1–4 months	Dilated cardiomyopathy
Arsenic trioxide	Days	Prolongation of QT interval on ECG leading to ventricular tachydysrhythmia (torsade de pointes)
Cyclophosphamide	Days	CHF, hemorrhagic pericarditis, tamponade, and death
5-Fluorouracil	Hours to days	Myocardial ischemia, cardiac conduction disorders, and cardiogenic shock

CHF = congestive heart failure; ECG = electrocardiogram; LVEF = left ventricular ejection fraction.

The neurologic toxicities of chemotherapeutics include central and peripheral manifestations. The acute manifestations of toxicity include both alterations in mental status and seizures, which occur from the systemic administration of high doses of nitrogen mustards (cyclophosphamide, ifosfamide, and chlorambucil), nitrosureas (lomustine), MTX, and vincristine. The inappropriate intrathecal administration of vincristine and MTX can cause central nervous system toxicity (Special Considerations: SC3). Patients with prior seizure disorders, delayed drug clearance, and altered drug pharmacokinetics (eg, nephrotic syndrome)⁵⁸ are at increased risk for seizures. L-Asparaginase, 5-FU, and procarbazine are associated with alterations in mental status.⁷⁷ Cerebellar ataxia is described in 5% of patients treated with 5-FU,⁵¹ and high-frequency ototoxicity can occur with cisplatin toxicity. The delayed onset manifestations of neurotoxicity from chemotherapeutics include leukoencephalopathy and peripheral neuropathies. Leukoencephalopathy from MTX typically presents as a delayed onset of behavioral and progressive dementia and is irreversible. Peripheral neuropathy involving both sensory and motor findings is seen with the Vinca alkaloids (vincristine) and bortezomib, but only sensory involvement is noted with cisplatin and paclitaxel.³⁹

Kidney failure from tubulointerstitial pathology can occur from MTX, cisplatin, ifosfamide, or nitrosureas in a dose-dependent manner. The nitrosurea semustine can cause glomerular injury leading to sclerosis. Kidney damage is attributed to the formation of insoluble intratubular precipitates of drug metabolites (7-OH MTX, the metabolite of MTX) or reactive intermediates (cisplatin, nitrosureas) that lead to cell death. The nitrosureas can also form isocyanate, which can impair DNA repair enzymes and lead to irreversible kidney damage.³⁸ The onset, severity, and reversibility of renal toxicity depend on the administered dose and the antineoplastic. For example, streptozocin is more nephrotoxic than the other nitrosureas, semustine, lomustine, and carmustine. Patients at increased risk for worsening renal function from these chemotherapeutics include those with prior kidney disease, increased age, salt and water depletion, hypotension, and concomitant use of nephrotoxic xenobiotics, such as aminoglycosides. Young children (younger than 5 years old) appear to

be more vulnerable to ifosfamide-induced proximal tubular toxicity leading to urinary loss of phosphate and bicarbonate than older patients.^{42,70} Also, patients with third-space fluid, such as ascites and pleural effusions, and aciduria are at increased risk for MTX-induced acute kidney injury (AKI) because of the prolonged half-life of the drug and the increased likelihood of the formation of insoluble precipitates in the renal tubules at a low urinary pH. The AKI from MTX, cisplatin, and streptozocin typically presents within 1 to 2 weeks, unlike in patients treated with semustine, who can present with renal compromise months to years after exposure.⁷⁸ Patients can develop fluid and electrolyte abnormalities from these chemotherapeutics, causing renal tubular disorders, and from vincristine, causing centrally mediated syndrome of inappropriate antidiuretic hormone secretion (SIADH) (Chaps. 19 and 36).

DIAGNOSTIC TESTING

The determinations of chemotherapeutic concentrations in clinical specimens are not routinely available, except for MTX. At certain research centers,¹¹ the testing for busulfan,⁶⁸ cisplatin (platinum),¹⁸ fluorouracil, vincristine,¹⁷ and topotecan can be available. These concentrations can be used to assist in confirming exposure and monitoring drug clearance but should not be relied on to determine initial management because of the difficulty in obtaining these tests and the limited ability to correlate the concentrations with clinical toxicity.

For certain chemotherapeutics, the presence of typical clinical manifestations strongly suggests their toxicity, for example, cisplatin (AKI and ototoxicity), Vinca alkaloids (peripheral neuropathy, central autonomic instability, and SIADH), anthracyclines (CHF and dilated cardiomyopathy), ifosfamide (encephalopathy and seizures), and MTX (AKI, mucositis, and pancytopenia). The diagnosis of a patient with toxicity from these xenobiotics is based on a historical evidence for exposure, clinical manifestations, and laboratory findings that support toxicity or exposure. For patients presenting with delayed onset symptoms, the association between toxicity and exposure requires an increased level of awareness to establish the causation.²⁶ Additional studies can be obtained to evaluate for specific disorders noted on the clinical examination, such as electromyography and nerve conduction studies for peripheral neuropathies, electroretinography for retinopathies, and echocardiography for cardiac dysfunction.

GENERAL MANAGEMENT

The initial management of these patients includes hemodynamic stabilization, decontamination, antidotal therapy, and enhanced elimination when feasible. Maximal benefits from antidotes and enhanced elimination can be obtained through their timely institution. Hypotension can result from dehydration, cardiac dysfunction, or sepsis. Patients with myocardial ischemia from 5-FU can be treated with coronary vasodilators, such as nitrates and calcium channel blockers. Seizures are treated with benzodiazepines, barbiturates, and propofol. Encephalopathy from high-dose ifosfamide has been treated with methylene blue (Antidotes in Depth: A42).⁴⁹ Patients with blood dyscrasias, including neutropenia and thrombocytopenia, should be evaluated for GI bleeding and infections. Those at risk for overwhelming sepsis should be started on broad-spectrum antibiotics and granulocyte colony-stimulating factor (G-CSF) as indicated. Oral activated charcoal can be administered to patients soon after an oral exposure to limit the gut bioavailability of the chemotherapeutic. Repeat oral doses of activated charcoal can enhance the clearance of MTX in patients with AKI or CKD.²³

Patients with vomiting are typically difficult to manage. Combination therapy involving multiple antiemetics is needed to treat patients exposed to chemotherapeutics with high emetogenic potential (eg, cisplatin, doxorubicin, cyclophosphamide, lomustine) or excessive doses of chemotherapeutics with low emetogenic potential (eg, Vinca alkaloids, fluorouracil). Therapy can include 5-HT₃ receptor antagonists, corticosteroids, dopamine receptor antagonists, a neurokinin-1 receptor antagonists, or benzodiazepines.⁴⁰ Serotonin receptor antagonists are effective for vomiting starting within 6 hours of exposure and are used with dexamethasone and aprepitant in patients with protracted vomiting. When the 5-HT₃ receptors are saturated, additional doses are no longer effective. Aprepitant, when used in combination with a corticosteroid, such as dexamethasone, is effective for managing delayed-onset vomiting, which can last for 5 days. Dopamine receptor antagonists, 5-HT₃ receptor antagonists, or dexamethasone at a higher dose can be used to treat breakthrough vomiting. Benzodiazepines can be used in this setting, but they are most effective for the prevention of vomiting. A basic metabolic panel, complete blood count, urinalysis, and ECG should be obtained for patients with a significant overdose to evaluate toxicity and to establish baseline values. Pregnant women exposed to chemotherapeutics require individualized care.⁴⁶ The patient's peripheral blood count should be followed for up to 2 weeks after a chemotherapeutic is administered because of the potential delayed onset of myelosuppression.

Gastrointestinal fluid losses from vomiting, diarrhea, and mucosal ulcerations can lead to salt and water depletion, which should be treated with IV fluids. IV fluids are important for patients with cisplatin and MTX toxicity to promote the renal elimination of toxic metabolites. Patients with cisplatin toxicity should be treated with 0.9% sodium chloride and an osmotic diuretic to maintain an adequate chloride gradient to promote the renal elimination of cisplatin. Urinary alkalization is indicated for patients with MTX toxicity to limit the precipitation of drug metabolites in the renal tubules.

Antidotal therapy is available for only a few xenobiotics, including anthracyclines (dexrazoxane), MTX (leucovorin, glucarpidase), cisplatin (amifostine, thiosulfate), 5-FU (uridine triacetate),⁴⁵ and ifosfamide (methylene blue, mercaptoethane sulfonate). Uridine triacetate as uridine triphosphate competes with 5-FU as fluorouridine triphosphate during RNA synthesis to limit toxicity (Fig. 50–3). These antidotes permit the use of higher doses of antineoplastics in cancer patients. However, patients with overdoses from antineoplastics can also benefit from the use of these antidotes, which should be initiated soon after the decision to treat has been made. Additional information regarding them can be found in Chaps. 51 and 52 and Antidotes in Depth: A10, A11, A39, and A42.

FIGURE 50–3. 5-Fluorouracil, capecitabine, and tegafur chemotherapeutic mechanisms of action and uridine triacetate antidotal rescue. 5'-DFCR = 5'-deoxy-5-fluorocytidine; 5'-DFUR = 5'-deoxy-5-fluorouridine; 5-FdUMP = fluorodeoxyuridine monophosphate; 5-FU = 5-fluorouracil; 5,10-methylene-FH4 = 5,10-methylenetetrahydrofolate; CYP2A6 = cytochrome P450, family 2, subfamily A, polypeptide 6; DHFR = dihydrofolate reductase; DHFU = 5,6-dihydrofluorouracil; DNA Pol = DNA polymerase; DPD = dihydropyrimidine dehydrogenase; dTMP = deoxythymidine monophosphate; dTTP = deoxythymidine triphosphate; dUMP = deoxyuridine monophosphate; FdUTP = fluorodeoxyuridine triphosphate; FH2 = dihydrofolate; FUDR = floxuridine; FUTP = fluorouridine triphosphate; RNA Pol = RNA polymerase; TKase = thymidine kinase; TPase = thymidine phosphorylase; TYMS = thymidylate synthase; UTP = uridine triphosphate. (Used with permission of Silas W. Smith, MD.)

The decision to use myeloid growth factors in patients with agranulocytosis depends on the severity and nature of the neutropenia, the anticipated speed of recovery, and the tumor type. Granulocyte-macrophage colony-stimulating factor (GM-CSF) has been used for several patients with overdoses such as cisplatin, melphalan, bleomycin, fluorouracil, and MTX.^{14,29,33–35,37,45,48,67} Typically, if promyelocytes and myelocytes are present in the bone marrow, neutrophil recovery will occur spontaneously in 4 to 7 days after the withdrawal of the offending antineoplastic.²⁰ However, when granulopoiesis is completely absent, neutrophil recovery cannot be expected for at least 14 days. The use of G-CSF or GM-CSF can accelerate neutrophil recovery during cytotoxic antineoplastic therapy. When myeloid precursors are present in the bone marrow, G-CSF can accelerate neutrophil recovery in 1 to 4 days. If myeloid precursors are absent, neutrophil recovery with G-CSF can take longer, but it will be enhanced. GM-CSF is indicated for use in neutropenic patients after

induction antineoplastic therapy for acute myelogenous leukemia because GM-CSF enhances the response of macrophages, neutrophils, and eosinophils. Serum concentrations of the antineoplastic should be below detection before institution of G-CSF to gain maximal response. Typically, G-CSF is initiated within 24 hours of the completion of the treatment cycle. The initial dose is 5 µg/kg/d IV or subcutaneously, and it should be continued beyond the expected white blood cell (WBC) nadir for approximately a 2 week course, although it can be prolonged for lomustine overdoses.^{1,72} The dose may be adjusted, depending on the patient's WBC response, but should be discontinued when the postnadir absolute neutrophil count is greater than 10,000 cells/mm³. Bone pain can be anticipated from the use of colony-stimulating factors, presumably because of the increase in cellularity in the marrow space. Additional side effects can be expected from GM-CSF therapy, including myalgia, fever, and pericarditis.

GM-CSF can produce a transient beneficial response in the WBCs in patients with aplastic anemia.¹² However, when the anemia is severe, the GM-CSF therapy is not effective. Another hematopoietic growth factor, erythropoietin (epoetin alfa and darbepoetin alfa), is approved for use in patients with anemia associated with cancer chemotherapy.^{7,57} Although the purpose of this therapy is to decrease the need for red blood cell transfusions, it does not replace the need for red blood cell transfusion when indicated.

CHEMOTHERAPEUTICS IN THE WORKPLACE

Pharmacists, nurses, physicians, and others involved in the preparation and dispensing of chemotherapeutics and those who may be exposed to the body fluids of patients treated with antineoplastics are at increased risk for toxicity. Several studies demonstrate they can be detected in the work environment and measured in workers,⁵⁹ and there is concern about the possible genotoxic effects from these exposures.⁶³ Workers may absorb these xenobiotics by the dermal, inhalational, or GI route. The factors determining the amount of worker exposure include the nature of the work, the amount of chemotherapeutic used, the frequency and duration of exposure, the physical and chemical nature of the chemotherapeutic, and the use of ventilated cabinets and personal protection equipment during the handling of these chemotherapeutics. The workplace guidelines for chemotherapeutics fall under the broader category of hazardous agents. The National Institute for Occupational Safety and Health (NIOSH) defines a “drug” as a “hazardous agent” if it is carcinogenic, teratogenic, genotoxic, associated with developmental or reproductive toxicity, or toxic to organs at low dose. A sample list of drugs considered to be hazardous by NIOSH is available.¹⁰

Regulatory and workplace recommendations for exposure levels and the waste management of these xenobiotics are available from various agencies and organizations. These recommendations are limited in scope because only a small number of xenobiotics or adverse health effects are adequately studied, and many xenobiotics do not meet the current definition for inclusion. The US Environmental Protection Agency (Resource Conservation and Recovery Act, 40 CFR §§260–279)⁵⁶ regulates nine chemotherapeutics (arsenic trioxide, chlorambucil, cyclophosphamide, daunomycin, melphalan, mitomycin C, naphthylamine mustard, streptozocin, and uracil mustard) and the equipment and devices associated with their preparation or delivery, as well as their disposal, as hazardous waste.⁵⁶ The current recommendations for worker safety with these xenobiotics in the workplace include the proper management of the work environment (eg, storage, handling, preparation, administration, use of personal protection equipment, decontamination, and waste disposal) and the institution of a medical surveillance program with approved laboratory testing.^{2,47,63}

SUMMARY

- The chemotherapeutics are a unique therapeutic class because their cytotoxicity is a direct effect.
- The majority of serious chemotherapeutic overdoses are iatrogenic, involving misreading of the product label, and errors in dosing and transcription of orders. A key element is the lack of familiarity of the health care provider with the use of these select xenobiotics.
- Clinical manifestations of chemotherapeutic toxicity depend on the mechanism of action, route of administration, and duration of exposure. The gut epithelium and bone marrow are extremely susceptible to toxicity because of their high mitotic activity. They are important because their failure will lead to overwhelming sepsis and death.
- Treatment remains primarily supportive in nature. The early institution of cytoprotectants, such as leucovorin and glucarpidase for MTX, amifostine for cisplatin, uridine triacetate for 5-FU, and dexrazoxane for anthracyclines, as antidotal therapy in overdosed patients can limit further toxicity. However, further work is needed to better define their optimal use in these situations.
- The best treatment for chemotherapeutic overdoses is prevention, which can be accomplished by maintaining a heightened awareness when working with these xenobiotics, educating patients and health care providers regarding their use, and providing increased skilled and standardized care.

51 CHEMOTHERAPEUTICS: METHOTREXATE

Richard Y. Wang

Methotrexate (MTX) is commonly used in the treatment of cancers and noncancerous conditions. Its immunosuppressive activity allows it to also be used for rheumatoid arthritis, organ transplantation, psoriasis, trophoblastic diseases, and therapeutic abortion.^{12,33}

Risk factors for MTX toxicity include impaired kidney function (primary route of drug elimination), third compartment spacing, ascites and pleural effusions, concurrent use of nephrotoxins (such as nonsteroidal antiinflammatory drugs (NSAIDs) aminoglycosides⁴²) and certain intravenous (IV) radiologic contrast dyes^{18,26}, age, folate deficiency, and concurrent infection.⁶⁵ MTX toxicity depends on the dose but even more on the duration of exposure.

PHARMACOLOGY

The therapeutic and toxic effects of MTX are based on its ability to limit DNA and RNA synthesis by inhibiting dihydrofolate reductase (DHFR) and thymidylate synthetase (Fig. 51–1). Thymidylate synthesis is inhibited by polyglutamic derivatives of MTX. DHFR reduces folic acid to tetrahydrofolate (FH4), which serves as an essential cofactor in the synthesis of purine nucleotides. Reduced folate is also required by thymidylate synthetase to serve as a methyl donor in the formation of thymidylate. Thymidylate is then used for DNA synthesis. MTX, a structural analog of folate, competitively inhibits DHFR by binding to the enzymatic site of action. This inhibits reduced folate production, which is necessary for nucleotide formation and DNA/RNA synthesis.

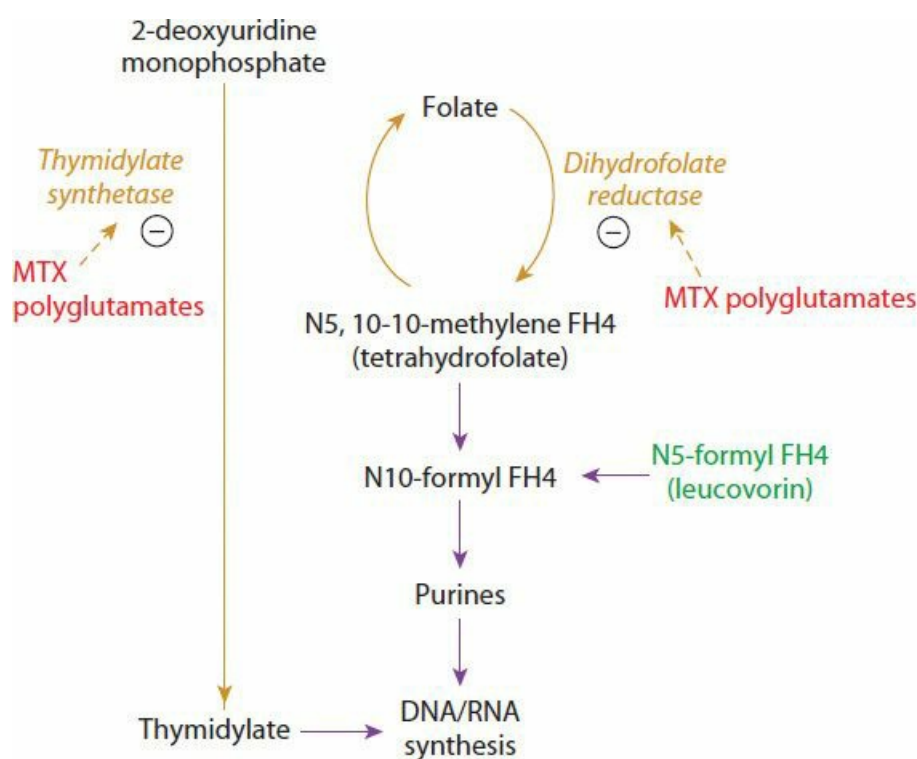

FIGURE 51–1. Mechanism of methotrexate (MTX) toxicity. MTX and MTX polyglutamates inhibit dihydrofolate reductase (DHFR) and thymidylate synthetase, which are necessary for DNA and RNA synthesis. Leucovorin bypasses DHFR blockade to allow for continued synthesis.

The bioavailability of MTX appears to be limited by a saturable intestinal absorption mechanism. At oral doses less than 30 mg/m², the absorption is 90%; at doses greater than 80 mg/m², the total absorption is less than 10% to 20%.⁹ The weekly adult dose used for the treatment of psoriasis and rheumatoid arthritis is low and can be administered orally. However, the dose used to induce abortion is higher (50 mg/m²) and must be administered parenterally to achieve an effective drug concentration. MTX dosing regimens for chemotherapy are variable but can be generally classified as low (40 mg/m²), moderate range, and high doses (1000 mg/m²). Conventional IV doses of up to 100 mg/m² can be administered without leucovorin rescue. Doses of 1000 mg/m² are considered potentially lethal. Much higher doses (2–3 g/m²) can be given when MTX is followed by leucovorin to prevent life-threatening toxicity. The mortality rate from high-dose MTX is approximately 6% and occurs primarily when MTX concentrations are not closely monitored.^{65,68}

Methotrexate has a triphasic plasma clearance. The initial plasma distribution half-life is short at 0.75 hours. The second half-life is 2 to 3.4 hours and represents renal clearance of the drug. The third phase has a half-life of about 8 to 10.4 hours and represents tissue redistribution into the plasma. This third phase can be prolonged in the setting of kidney failure and is associated with bone marrow and gastrointestinal (GI) toxicity. The volume of distribution is 0.6 to 0.9 L/kg, and protein binding is 50%. Healthy kidneys eliminate 50% to 80% of MTX unchanged within 48 hours of administration. When the creatinine clearance is less than 60 mL/min, MTX clearance is delayed.^{58,70}

PATHOPHYSIOLOGY

At high doses, drug and insoluble drug metabolites (7-hydroxy methotrexate {7-OH-MTX} and 2,4-diamino-N10-methylpteroic acid {DAMPA}) accumulate and may precipitate in the renal tubules, causing reversible acute tubular necrosis. MTX is one-tenth as soluble at a pH of 5.5 as it is at a pH of 7.5.^{9,59} Expressed another way, the serum concentration threshold for nephrotoxicity is 2.2 mmol/L when the urine pH is 5.5 and 22 mmol/L when the urine pH is 6.9. Thus, patients who are either inadequately hydrated or have not had urinary alkalinization are at risk for acute kidney failure from high-dose MTX treatment.^{3,34} MTX is excreted unchanged in the urine by both glomerular filtration and active tubular secretion. Folic acid blocks renal MTX reabsorption and can enhance elimination during leucovorin rescue.²⁷ A small amount of MTX is metabolized intracellularly to polyglutamate derivatives, which inhibit DHFR and thymidylate synthetase and are believed to be responsible for the persistent cytotoxic effect of MTX because they do not easily diffuse outside of the cell.

CLINICAL MANIFESTATIONS

In the course of MTX therapy, a variety of disorders can occur, resulting from either increased patient susceptibility to toxicity or excessive administration. The clinical manifestations of MTX toxicity include stomatitis, esophagitis, kidney failure, myelosuppression, hepatitis, and central nervous system dysfunction. In a group of 23 patients who received 45 courses of high-dose MTX therapy with leucovorin rescue, the most commonly observed signs included increased aspartate aminotransferase (AST) or alanine aminotransferase (ALT) (81%), nausea and vomiting (66%), mucositis (33%), dermatitis (18%), leukopenia (11%), thrombocytopenia (9%), and creatinine elevation (7%).⁵⁵

Nausea and vomiting, considered rare after low-dose cancer therapy (40 mg/m²), typically begin 2 to 4 hours after high-dose therapy (1000 mg/m²) and last for about 6 to 12 hours. Mucositis, characterized by mouth soreness, stomatitis, or diarrhea, usually occurs in the first week of therapy, continues to evolve in the second week of therapy, and can last for 4 to 7 days. Other GI effects resulting from MTX therapy include pharyngitis, anorexia, GI hemorrhage, and toxic megacolon.⁶ Hepatocellular toxicity, as identified as increased AST (>1000 IU/L) or ALT (>1000 IU/L), and hyperbilirubinemia, can occur with both acute and chronic therapy.^{47,49} It is usually associated with high dose regimens. Laboratory abnormalities improve within 1 to 2 weeks of discontinuation of MTX. The mechanism is incompletely understood, but toxicity is attributed to reduced liver folate stores.⁷ Factors associated with hepatotoxicity include sustained high serum concentrations, increased cumulative dosages, chronic therapy, and host factors such as an increase in age, obesity, diabetes, and alcoholism.⁷¹

Pancytopenia usually occurs within the first 2 weeks after an acute exposure. Pancytopenia can also occur with chronic MTX therapy for rheumatoid arthritis and psoriasis.^{16,40,47,57}

When used in low-dose IV doses of 40 to 60 mg/m², MTX is not associated with appreciable nephrotoxicity. However, at doses greater than 5000 mg/m² (~130 mg/kg for an adult), several investigators report severe kidney damage, with oliguria, azotemia, and kidney failure.⁸ The kidney function can normalize over time. Patients at risk for nephrotoxicity include elderly adults; those with underlying kidney disease defined as a glomerular filtration rate of less than 50 mL/min; and those who receive concurrent drug therapy that can delay MTX excretion, which includes xenobiotics that reduce renal blood flow such as NSAIDs, nephrotoxins such as cisplatin and the aminoglycosides, and weak organic acids such as salicylates and piperacillin that inhibit renal secretion.^{32,65}

The neurologic complications associated with either high-dose systemic MTX therapy or intrathecal administration are the most consequential manifestations. The incidence of neurologic toxicity from high-dose MTX therapy is approximately 5% to 15%.³⁵ The manifestations of toxicity usually occur from hours to days after the initiation of therapy and include hemiparesis, paraparesis, quadraparesis, seizures, and dysreflexia.^{35,46,66,69} These events are reversible to varying degrees.² Clinical findings occurring within several hours (usually within 12 hours) of therapy are attributed to chemical arachnoiditis, and they include acute onset of fever, meningismus, pleocytosis, and increased cerebrospinal fluid (CSF) protein concentration.²⁸ Leukoencephalopathy is associated with the onset of behavioral disorders and progressive dementia from months to years after treatment and is irreversible, although manifestations presenting soon after treatment can be reversible depending on the extent of involvement.^{5,74} Patients with increased age and prior cranial radiation are at increased risk for this disorder.²³ Patients with leukoencephalopathy have findings consistent with edema and demyelination or necrosis of the white matter on computed tomography (CT) and magnetic resonance imaging (MRI) of the brain.⁵

DIAGNOSTIC TESTING

Serum MTX concentrations are monitored during therapy to limit toxicity. For example, patients with a serum concentration greater than 1.0 $\mu\text{mol/L}$ at 48 hours after treatment are considered at risk for bone marrow and mucosal toxicities.⁶⁵ The measurement of MTX concentrations in the clinical setting is routinely conducted using an enzyme immunoassay or fluorescence polarization immunoassay (FPIA). These measurements can be performed on serum, plasma, and CSF. The presence of MTX metabolites, such as 7-OH-MTX and DAMPA, folic acid, and certain drugs, such as trimethoprim and aminopterin, can diminish the specificity of the analytical method for MTX.^{4,11,19,53,60} The amount by which these xenobiotics affect the MTX concentration depends on the assay. Leucovorin demonstrated a crossreactivity for MTX of less than 1% at a concentration of 1000 $\mu\text{mol/L}$ with the FPIA (monoclonal antibody {MAB}) method¹ and approximately 8% at a concentration of 1.69 $\mu\text{mol/L}$ with a modified enzyme immunoassay method.¹⁰ The advantages of high-performance liquid chromatography (HPLC) over these other methods include improved sensitivity, specificity, and ability to detect metabolites; however, HPLC takes longer to run than the routine clinical methods because it is not an automated procedure. When patients are treated with glucarpidase (carboxypeptidase) (Antidotes in Depth: A11), it is preferable to use the HPLC method to measure MTX because of the presence of metabolites. The FPIA method with MABs is not recommended for use in patients who have developed antibodies to mouse MABs or elevated concentrations of DAMPA.⁴¹

An elevated CSF MTX concentration ($>100 \mu\text{mol/L}$) is indicative of an excessive intrathecal dose or delayed CSF outflow obstruction.⁵⁰ Radiologic imaging of the brain, such as CT and MRI, can be obtained to evaluate for meningeal inflammation, demyelination and necrosis of the white matter, or other pathologies such as a cerebrovascular accident.

MANAGEMENT

In the event of an oral overdose of MTX, the initial concern should be GI decontamination. Activated charcoal adsorbs MTX and should be administered as soon as possible to limit absorption.²⁴ The administration of multiple-dose activated charcoal or cholestyramine^{17,62} can significantly decrease the elimination half-life of MTX by interrupting the enterohepatic circulation.^{21,24} This approach can increase MTX clearance but is of most benefit to patients with diminished creatinine clearance.

Adequate hydration with 0.9% sodium chloride solution as well as urinary alkalization with IV sodium bicarbonate (to urine pH of 7 to 8) (Antidotes in Depth: A5) is also important to prevent kidney failure that results from the precipitation of MTX and metabolites.¹³ The complete blood count should be monitored on days 7, 10, and 14 to assess the impact on the bone marrow.⁴³ Granulocyte-macrophage colony-stimulating factor (GM-CSF) was used in a patient with a chronic MTX overdose and pancytopenia.⁶⁴ The patient had a serum MTX concentration of 1.25 $\mu\text{mol/L}$ on admission and was in kidney failure. Bone marrow biopsy showed promyelocytes but no mature white cells and a marked reduction of megakaryocytes. Because of deteriorating conditions, GM-CSF (125 $\mu\text{g/m}^2/\text{d}$) was administered when the MTX concentration fell below the reference limit for toxicity. Seven days after the initiation of GM-CSF, the white blood cell count rose and reached normal values within 10 days.

Patients presenting with meningismus or altered mental status after MTX therapy require an initial MRI of the brain and then CSF analysis for infection.³⁸ Although not considered standard, the CSF can be assayed for MTX if excessive exposure to this compartment is suspected. The CSF MTX concentration is about 0.1 mol/L ($1 \times 10^5 \mu\text{mol/L}$) and lasts for 48 hours after an IV MTX dose of 1500 mg/m^2 and 100 mol/L ($1 \times 10^8 \mu\text{mol/L}$) for the peak therapeutic concentration after a 12-mg intrathecal MTX dose.⁵¹ MRI of the brain can demonstrate a high signal throughout the pachymeningeal (dura mater) region, which is consistent with chemical meningitis,²⁰ or a high signal of the white matter with a decreased

diffusion coefficient in a diffusion-weighted image to indicate the presence of edema, which is an early finding of leukoencephalopathy.

ANTIDOTES

The available rescue agents for MTX toxicity include folinic acid (leucovorin) (Antidotes in Depth: A10) and glucarpidase (carboxypeptidase) (Antidotes in Depth: A11). The effectiveness of these therapies depends on both the timing of administration and the dose, which warrants the monitoring of serum MTX concentrations during the use of these antidotes. Folinic acid rescue therapy limits bone marrow and GI toxicity by allowing essential biochemical processes that are dependent on reduced folates to continue. The purpose of the initial dose of leucovorin is to achieve a serum concentration equal to the MTX; subsequent doses should be adjusted according to serum MTX concentrations at 12, 24, and 48 hours after exposure (Fig. 51–1).^{39,60} Leucovorin treatment is continued until the MTX concentration is less than 0.01 $\mu\text{mol/L}$.¹² In patients with marrow toxicity and no cancer, leucovorin therapy should be continued until marrow recovery occurs even if serum MTX is no longer detectable⁴⁵ because intracellular MTX activity can still be ongoing because of the presence of cytosolic MTX polyglutamates. Among 36 patients undergoing MTX therapy (the amount varied from 2.0–13.0 mg of MTX per week) for rheumatoid arthritis, all of these patients had indirectly detectable MTX polyglutamates in their red blood cells and nondetectable MTX in the serum (FPIA, MAB).^{29,30}

Glucarpidase (carboxypeptidase G₂, Voraxaze) is a recombinant bacterial enzyme that is used as a rescue therapy to inactivate MTX by hydrolyzing it to DAMPA and glutamate. Glucarpidase is available for use as an adjunctive therapy in patients receiving high-dose MTX and those experiencing MTX toxicity or who are at risk for MTX toxicity (diminished kidney function or delayed MTX clearance based on serum MTX concentrations). After glucarpidase therapy, serum MTX concentrations need to be monitored because residual concentrations of MTX in the blood after initial enzymatic therapy can result from an inadequate dose of glucarpidase. This occurs in patients with large MTX exposures or the redistribution of MTX from tissue stores to the blood compartment.^{11,60,72} Glucarpidase can also be successfully administered intrathecally to reduce elevated MTX concentrations in the cerebrospinal space (Special Considerations: SC3).⁷³

EXTRACORPOREAL ELIMINATION

There are several reports of the use of hemodialysis or hemoperfusion (or both) for patients with MTX toxicity.^{37,48,56,67,70} Although the volume of distribution (0.6–0.9 L/kg) and protein binding (50% that is not concentration dependent) suggest that MTX is dialyzable, older clinical evidence suggested otherwise.⁶⁴ In one report, less than 10% of an initial 700 mg dose of MTX was cleared in 12 sessions of hemodialysis.⁶⁷ The measured clearance was only 38 mL/min, which can be compared with 5 mL/min for peritoneal dialysis,²⁵ 0.28 to 24 mL/min for continuous venovenous hemodiafiltration,^{36,39} and 180 mL/min for normal renal clearance.⁴⁴ Using plasma exchange transfusion to remove MTX is not recommended because MTX has limited protein binding, limiting any potential efficacy of this procedure.^{8,39,52,67}

Acute intermittent hemodialysis with a high-flux dialyzer membrane (F-80B Fresenius Dialyzer) yielded an effective mean serum MTX clearance of 92 ± 10.3 mL/min in six patients with kidney failure that was a result of either chronic disease or high-dose MTX therapy.⁷⁰ These patients received high-dose MTX therapy and had predialysis serum MTX concentrations ranging from 1.45 to 1813 $\mu\text{mol/L}$. The time of dialysis initiation after MTX treatment was from 1 hour to 6 days in these patients. A postdialysis serum MTX concentration of 0.3 $\mu\text{mol/L}$ was used as an end point for dialysis. The reported MTX clearance by this technique closely approximates normal renal MTX clearance and is indicated to enhance the clearance of MTX in patients with diminished renal clearance and an elevated serum MTX concentration.⁵⁸

Charcoal hemoperfusion removed more than 50% of MTX in four patients with impaired renal MTX clearance during high-dose MTX therapy.¹⁵ This was thought to have prevented severe skin and mucosal toxicity. Sequential hemodialysis and hemoperfusion were used for a patient with substantial MTX toxicity.²⁴ These procedures decreased the half-life of elimination from 45 hours to 7.6 hours. In experimental animals, hemoperfusion significantly reduced the terminal half-life of MTX. In surgically anephric dogs, hemoperfusion decreased the half-life from more than 20 hours to 1.3 hours.³¹ Consequently, hemoperfusion is recommended over hemodialysis when it is available; otherwise, high-flux hemodialysis is preferred.⁵⁶

In vitro studies indicate that the toxic effects of 100 $\mu\text{mol/L}$ of MTX cannot be reversed by 1000 $\mu\text{mol/L}$ of folinic acid.⁵⁴ This suggests the need for extracorporeal elimination after massive doses or enzymatic cleavage (or both) to lower persistent serum MTX concentrations of greater than 100 $\mu\text{mol/L}$.⁵⁶ It is important to perform high-flux hemodialysis early before distribution into tissues. Rebound of MTX concentrations from tissues can be expected after hemodialysis, which can begin at 2 hours after dialysis and plateau at 16 hours.^{22,25,70} Patients who are at the greatest risk for developing MTX toxicity despite folinic acid treatment should be considered for glucarpidase therapy. This includes patients with progressively diminishing renal clearance.⁶⁵ High-flux hemodialysis can offer the additional benefit of correcting fluid and

electrolyte disorders resulting from kidney failure. Other treatment options to limit additional organ toxicity, including leucovorin and urinary alkalization, should be continued during extracorporeal MTX removal. Folic acid is water soluble and can be removed by hemodialysis.^{14,56,61,63} This is probably also applicable for folinic acid, and replacement doses of leucovorin postdialysis should be considered.

SUMMARY

- The number of patients with MTX exposures and resultant toxicity is anticipated to increase because of the expanding therapeutic indications and available multiple formulations of this antineoplastic.
- Clinicians need to have a greater awareness of the clinical presentations, acute and chronic, and management of MTX toxicity to improve outcomes.
- Patients with associated chronic illnesses, diminished renal clearance, and chronic toxicity are at greatest risk for increased morbidity from overwhelming sepsis.
- Management includes supportive care, monitoring serum MTX concentrations, urinary alkalization to limit kidney toxicity, enhanced elimination, and antidotal therapy with leucovorin and enzymatic cleavage with glucarpidase when indicated.
- The early recognition of these patients and institution of these therapies can offer the patient the best outcome.

A10 ANTIDOTES IN DEPTH

Folates: Leucovorin (Folinic Acid) and Folic Acid

Mary Ann Howland

Folic Acid

Folinic Acid

Folates refer to the metabolically active reduced forms of folic acid, including dihydrofolate and tetrahydrofolate. These folates are vital to cellular biochemistry, including the synthesis of purines and DNA. Folic acid must be reduced in vivo by dihydrofolate reductase to tetrahydrofolate. Dihydrofolate reductase inhibitors such as methotrexate prevent this reduction. Leucovorin (folinic acid) and levoleucovorin, and compared with folic acid, they do not require dihydrofolate reductase for activation. Therefore, either leucovorin or levoleucovorin is the primary antidote for a patient who receives an overdose of methotrexate or another dihydrofolate reductase inhibitor.

Methanol is metabolized to the active and toxic formic acid. Folates, including folic acid and leucovorin, speed up the conversion of formic acid to nontoxic metabolites. Because methanol does not interfere with the synthesis of tetrahydrofolate, either folic acid or leucovorin is acceptable for a patient poisoned by methanol who necessitates enhanced formate metabolism. Preliminary evidence also suggests a role for folic acid to enhance arsenic elimination.

HISTORY

In the early 1930s when Lucy Wills went to Bombay to study pregnant textile workers with macrocytic anemia, she found that a yeast extract given to these poor people with a nutritionally deficient diet corrected and prevented their anemia.¹¹ Mitchell isolated the active ingredient from spinach in 1941 and named it folic acid from the Latin folium meaning leaf.¹¹ Subsequently, folic acid was synthesized and its chemical structure identified. Since then, the many roles of folate and natural or induced folate deficiency continue to be studied.

PHARMACOLOGY

Folic acid (pteroylglutamic acid), an essential water-soluble vitamin, consists of a pteridine ring joined to PABA (para-aminobenzoic acid) and glutamic acid.¹⁰ Folic acid is the most common of the many folate congeners that exist in nature and perform essential cellular metabolic functions. Folic acid is often called vitamin B₉. After absorption, folic acid is reduced by dihydrofolic acid reductase (DHFR) to dihydrofolic acid and then tetrahydrofolic acid (THF), which accepts one carbon groups. Tetrahydrofolic acid serves as the precursor for several biologically active forms of folic acid, including 5-formyltetrahydrofolic acid (5-formyl THF), which is best known as folinic acid, leucovorin, and citrovorum factor. These biologically active forms of folate are enzymatically interconvertible and function as cofactors, providing the one carbon groups necessary for many intracellular metabolic reactions, including the synthesis of thymidylate and purine nucleotides, which are essential precursors of DNA.^{29,32,36,38,43} The minimum daily requirement of folic acid is normally 50 µg, but pregnant women and nutritionally deprived, acutely ill patients may require 100 to 200 µg.^{10,12}

Leucovorin is a mixture of the active and inactive diastereoisomers of 5-formyl THF of which the levo form is active and available as levoleucovorin.⁶ Both are available as the calcium salt, with the same chemical formula, C₂₀H₂₁CaN₇O₇, and a molecular weight (MW) of 511 Da. Both are rapidly metabolized to several active folates, including 5-methyltetrahydrofolate (5-CH₃-THF). The dose of levoleucovorin is half of leucovorin.

After a DHFR inhibitor such as methotrexate inhibits the formation of tetrahydrofolic acid, the intracellular machinery for the synthesis of indispensable thymidylate and purine nucleotides comes to a halt, and DNA production ceases. Leucovorin and levoleucovorin are biologically active forms of folic acid and bypass this inhibition of DHFR caused by methotrexate.

Folate catalyzes the formation of carbon dioxide and water from formic acid, the final metabolic step in methanol elimination. Because there is no inhibition of the formation or recycling of active folate, either folic acid or leucovorin is beneficial.

Early investigations suggest that folic acid may aid in the methylation and subsequent elimination of arsenic. Folate supplementation in folate-deficient subjects was done to enhance the elimination of arsenic and potentially decreased chronic arsenic toxicity.^{5,7,8,30} Studies remain to be performed to determine whether folate supplementation in folate-replete individuals is beneficial.

Leucovorin Pharmacokinetics

Whereas leucovorin is naturally formed in the body as the active (l) isomer, the commercial preparation is the racemic mixture, which means it consists of equal amounts of the inactive (d) and active (l) isomers. The pharmacokinetics of the racemic mixture of leucovorin and its active metabolite were studied after a single intravenous (IV) infusion and as a constant infusion in normal human volunteers.^{39,40} During constant infusion of 500 mg/m²/d, the steady-state concentration for the active isomer was 2.33 µmol, the half-life was 35 minutes, and the volume of distribution (Vd) was 13.6 L. The active isomer is metabolized to an active metabolite (l-5-CH₃-THF) that achieved a steady-state concentration of 4.85 µmol and a half-life of 227 minutes. Similar values were achieved for half-life and Vd after single IV doses ranging from 25 to 100 mg. The inactive d-isomer achieved higher concentrations and had a much longer half-life with oral administration, which is saturable and stereoselective, resulting in absorption of the active isomer that is four to five times greater than that of the inactive isomer. Studies of stereospecific oral absorption demonstrate that 100% of the l-leucovorin is absorbed, but only 20% of the d-leucovorin is absorbed at this dose.¹⁹ One study detected no adverse effects of the inactive isomer on the intracellular uptake of the active isomer and concluded that giving the active isomer provided no pharmacokinetic advantage over the racemic mixture.³⁵

Two hundred milligrams of levoleucovorin was compared to 400 mg of leucovorin, each administered as a 2 hour IV infusion as a crossover study in 40 healthy volunteers. The area under the curve and the maximum serum concentrations of l-5-CH₃-THF were similar for both.

Preliminary evidence suggests that l-5-CH₃-THF enters the CSF after systemic administration of both leucovorin and levoleucovorin. However, the concentration achieved is one to three orders of magnitude less than is normally obtained after intrathecal methotrexate. Intrathecal administration of leucovorin and levoleucovorin is contraindicated.

The pharmacokinetics of IV leucovorin was compared with intramuscular (IM) and oral administration in male volunteers given 25 mg. The mean peak of the active 1-5-CH₃-THF concentration was 258 ng/mL (5.5×10^{-1} μmol/L) at 1.3 hours after IV administration compared with 226 ng/mL at 2.8 hours for IM and 367 ng/mL at 2.4 hours for oral administration.

The pharmacokinetics of orally administered leucovorin was studied in healthy, fasted male volunteers in single doses ranging from 20 to 100 mg and 200 mg IV over 5 minutes compared with 200 mg orally.^{23,31} Bioavailability decreased from 100% for the 20-mg dose to 78% for the 40 mg dose and ultimately to 31% for the 200 mg dose. A microbiologic assay was used to measure total tetrahydrofolates (reduced and active folates). Normal serum folate concentrations are approximately 0.05 μmol/L.¹⁴ The 200 mg oral dose produced a peak serum concentration of 1.82 μmol/L compared with 0.66 μmol/L for the 20-mg oral dose and 27.1 μmol/L for the 200 mg IV dose.^{23,31}

ROLE IN METHOTREXATE TOXICITY

Methotrexate, an antimetabolite, is a structural analog of folic acid, differing only in the substitution of an amino group for a hydroxyl group at the number 4 position of the pteridine ring (Chap. 51). Methotrexate binds to the active site of DHFR, rendering it incapable of reducing folic acid to its biologically active forms and incapable of regenerating the necessary active forms required for the synthesis of purine nucleotides and thymidylate.³⁷ At physiologic pH, the binding between methotrexate and DHFR is competitive, with an inhibition constant of about 1 μmol/L.³⁴ Leucovorin is a reduced, active form of folate. As such, it does not require DHFR for enzymatic interconversion to the form required for purine nucleotide and thymidylate formation. Folic acid is unable to counteract methotrexate toxicity because after methotrexate therapy, DHFR is unavailable to convert folic acid to an active reduced form. Leucovorin rescue is the term used to describe the practice of limiting the toxic effects of high-dose methotrexate therapy.

ROLE IN METHANOL TOXICITY

Monkeys experimentally made folate deficient develop methanol toxicity at lower methanol concentrations.²⁴ Administering folic acid to normal monkeys accelerates formate metabolism.²⁴ Pretreatment with folic acid or leucovorin decreased both formate concentrations and the accompanying metabolic acidosis without affecting the rate of methanol elimination.²⁴ Leucovorin remained effective in hastening the metabolism of formate when given 10 hours after methanol administration.²⁷

The hepatic concentrations of total folate, leucovorin, and folate dehydrogenase (which increases leucovorin concentrations) are all diminished in methanol poisoned humans.¹⁶ In an analysis of a single methanol-poisoned patient who was given folic acid, ethanol, and hemodialyzed, the half-life of formate was 1.1 hours.²⁸ In another methanol poisoned patient treated without folic acid, the formate half-life was 2.8 hours.¹³ These comparative data are inadequate to draw definitive conclusions but may support the therapeutic role of folate in addition to that of fomepizole (Antidotes in Depth: A30) and hemodialysis.

ROLE IN ARSENIC TOXICITY

Arsenic contamination of drinking water has plagued millions, causing increased manifestations of chronic arsenic toxicity, including cancer and cardiovascular, dermatologic, and neurologic problems. Arsenic is methylated to monomethylarsonic acid (MMA) and then to dimethylarsinic acid (DMA). Early evidence suggests that nutritional deficiencies facilitate arsenic methylation, encouraging further study of folate supplementation along with other nutrients with the hope of diminishing the chronic health effects of arsenic toxicity.^{5,7,8,30} The absolute methylation amount and product probably also depends on the degree of upregulation.^{9a}

ADVERSE EFFECTS AND SAFETY ISSUES

Reports of adverse reactions to parenteral injections of folic acid, leucovorin, or levoleucovorin are uncommon. However, adverse reactions may include allergic or anaphylactoid reactions.¹⁰ Seizures are rarely associated with leucovorin or levoleucovorin administration.^{6,25} The calcium content of leucovorin and levoleucovorin warrants a slow IV infusion at a rate not faster than 160 mg/min in adults. There is 0.004 mEq of calcium per milligram of leucovorin calcium injection. Extremely large doses of leucovorin on the order of 1000 mg every 3 hours might lead to hypercalcemia.⁴⁴ Neither leucovorin nor levoleucovorin should be administered intrathecally.^{15,18,33,42}

Leucovorin and levoleucovorin are not antidotes for 5-fluorouracil (5-FU), and both can enhance both the therapeutic and toxic effects of fluoropyrimidines such as 5-FU.^{19,22} Both leucovorin and levoleucovorin are readily converted to 5,10-

methylenetetrahydrofolate, which enhances the binding of the active metabolite of fluorouracil to thymidylate synthase, thereby potentiating the inhibition.

Many protocols recommended separating leucovorin and levoleucovorin from glucarpidase by 2 hours (Antidotes in Depth: A11); otherwise, leucovorin acts as a substrate for glucarpidase.

There is a potential for dosing errors when interchanging leucovorin and levoleucovorin. The dose of levoleucovorin is half the dose of leucovorin.

PREGNANCY AND LACTATION

Leucovorin and levoleucovorin are Food and Drug Administration (FDA) pregnancy category C drugs. Human studies are lacking, and animal reproductive studies have not been conducted. Breast milk excretion is unstudied.

Folic acid is an FDA category A drug and is safe during pregnancy and compatible with breastfeeding.

DOSING AND ADMINISTRATION

After overdose of methotrexate, a dose of leucovorin estimated to produce the same plasma concentration as the methotrexate dose should be given as soon as possible, preferably, within one hour. One mole of methotrexate weighs 455 Da, and 1 mol of leucovorin calcium weighs 511 Da, with the MW of the leucovorin portion equal to 471 Da. Because of the safety of leucovorin and because of the toxicity of methotrexate, underdosing leucovorin should be avoided. Although serum methotrexate concentrations are often closely followed in patients on diverse oncologic regimens,^{2,3} in the overdose setting, or in methotrexate toxicity related to treatment for tubal pregnancies, it is inappropriate to wait for a serum concentration before initiating treatment with leucovorin.¹ The toxic threshold for methotrexate is reported to be 1×10^{-8} mol/L (0.01 μ mol/L or 10 nmol/L).⁴ Normal serum folic acid concentrations are in the range of 13 to 43 nmol/L. If the patient's exposure to methotrexate is not for therapeutic purposes there is no need to permit any methotrexate to remain unantagonized by leucovorin.

As an example, if a child unintentionally ingests 100 (2.5 mg) methotrexate tablets for a total dose of 250 mg, only part of this dose is absorbed because methotrexate absorption is saturable.⁹ The bioavailability of methotrexate decreases from 100% with doses less than 30 mg/m² to approximately 10% to 20% with doses greater than 80 mg/m². In this case, it is safe to assume that a bioavailability of 50% would result in an absorbed dose of methotrexate of less than 125 mg. For this exposure, an IV dose of 125 mg of leucovorin should be given over 15 to 30 minutes. This dose of IV leucovorin would be expected to produce serum concentrations in excess of that of the methotrexate, given that the Vd of leucovorin is about 25% less than methotrexate and the MWs are similar. This dose of IV leucovorin should be repeated every 3 to 6 hours until the serum methotrexate concentration is less than 0.05 μ mol/L, preferably zero. This differs from recommendations in patients receiving methotrexate therapeutically (see later discussion). The methotrexate half-life may vary from 5 to 45 hours, depending on the dose and the patient's kidney function. For this reason, leucovorin therapy should be continued for 12 to 24 doses (3 days) or longer if methotrexate concentrations are unavailable. Patients who may develop third-space storage in ascites or pleural effusions may also require leucovorin dosing for an extended period of time. Patients with bone marrow toxicity require more prolonged dosing because plasma half-lives of methotrexate do not reflect persistent intracellular concentrations.

Systemic Methotrexate Toxicity

The routine dose of leucovorin for "leucovorin rescue" after high-dose methotrexate therapy with doses of 12 to 15 g/m² ranges from 10 to 25 mg/m² IM or IV every 6 hours for 72 hours to 150 mg/m² every 3 hours in patients with renal compromise and delayed elimination. If a neonate must be treated, a benzyl alcohol-free preparation must be used because of the toxicity of benzyl alcohol in neonates (Chap. 55).⁴¹ For methotrexate overdoses, equimolar serum leucovorin concentrations should provide adequate protection, but because precise determinations are invariably delayed, leucovorin administration should be initiated without delay.

As a rough guide, a single dose of 25 mg of IV leucovorin in an adult produces a peak concentration of the active 1-5-CH₃-THF metabolite of approximately 258 ng/mL, which is 0.55 μ mol/L.¹⁹ A dosage of about 150 mg every 4 hours in an adult achieves a steady-state concentration of about 4.85 μ mol/L.³⁹ And although the dose of leucovorin can be as high as 1000 mg/m² every 6 hours, this is rarely warranted and cannot adequately compete with serum concentrations of methotrexate above 100 μ mol/L under these circumstances, glucarpidase should be strongly considered. An IV leucovorin dose of 150 mg/m² every 3 to 6 hours should be effective in all but the most severe overdoses and should be administered IV as soon as possible over 15 to 30 minutes but not faster than 160 mg/min in adults because of the calcium content. This dose should be continued a minimum of several days or until the serum methotrexate concentration falls below 0.05 μ mol/L in the absence of bone marrow toxicity. One case series of 11 patients receiving methotrexate over 4 hours at 10 to 12 g/m²

for osteosarcoma or 3.5 g/m^2 for central nervous system lymphoma required high-dose leucovorin rescue for methotrexate concentrations at high risk for toxicity at 24, 48, or 72 hours, usually because of acute kidney injury. The dosage of leucovorin ranged from 0.24 to 10 g/day and was titrated downward as the methotrexate concentration fell. It took an average of 11 ± 3 days for the methotrexate concentration to drop below $0.1 \text{ } \mu\text{mol/L}$ (Table A10–1).

TABLE A10-1. Guidelines for Leucovorin Dosage and Administration^a

<i>Clinical Situation</i>	<i>Laboratory Findings</i>	<i>Leucovorin Dosage</i>
Normal methotrexate elimination	Serum [methotrexate] $\sim 10 \text{ } \mu\text{mol/L}$ at 24 hours after administration, $1 \text{ } \mu\text{mol/L}$ at 48 hours, and $<0.2 \text{ } \mu\text{mol/L}$ at 72 hours	15 mg PO, IM, or IV every 6 hours for 60 hours (10 doses starting at 24 hours after the start of methotrexate infusion)
Delayed late methotrexate elimination	Serum [methotrexate] remaining $>0.2 \text{ } \mu\text{mol/L}$ at 72 hours and $>0.05 \text{ } \mu\text{mol/L}$ at 96 hours after administration	Continue 15 mg PO, IM, or IV every 6 hours until [methotrexate] is $<0.05 \text{ } \mu\text{mol/L}$
Delayed early methotrexate elimination or evidence of acute renal injury	Serum [methotrexate] of $\geq 50 \text{ } \mu\text{mol/L}$ at 24 hours or $\geq 5 \text{ } \mu\text{mol/L}$ at 48 hours after administration or a $\geq 100\%$ increase in serum [creatinine] at 24 hours after methotrexate administration (eg, an increase from 0.5 to $\geq 1 \text{ mg/dL}$)	150 mg IV every 3 hours until methotrexate level is $<1 \text{ } \mu\text{mol/L}$; then 15 minutes IV every 3 hours until [methotrexate] is $<0.05 \text{ } \mu\text{mol/L}$

^aLeucovorin should not be administered intrathecally.

IM = intramuscular; IV = intravenous; PO = oral.

The package insert for leucovorin rescue after high-dose methotrexate as well as the methotrexate package insert suggest the following guidelines when methotrexate concentrations are drawn 24 hours or more after the start of the methotrexate infusion (Table A10–1):^{19,26}

An IV leucovorin dose of 100 mg/m^2 every 3 to 6 hours should be effective in all but the most severe overdoses. A constant IV infusion of $21 \text{ mg/m}^2/\text{h}$ has been safely administered for 5 days. Figure A10–1 offers a nomogram for pharmacokinetically guided rescue after high-dose methotrexate.² A transition to oral administration of leucovorin depends on the serum concentration of methotrexate and whether adequate serum concentrations of leucovorin can be achieved orally. In adults, a 200 mg oral dose of leucovorin produces a peak serum concentration of $1.82 \text{ } \mu\text{mol/L}$ compared with $27.1 \text{ } \mu\text{mol/L}$ with a 200 mg IV dose.

FIGURE A10–1. Example of a nomogram developed by Bleier² for pharmacokinetically guided leucovorin rescue after high-dose methotrexate (MTX) administration.

Levoleucovorin, the active l isomer of folinic acid, is available and should be dosed at half the dose of the racemate leucovorin.⁶

Administration of activated charcoal (AC) precludes the subsequent administration of oral leucovorin. In addition to leucovorin, other modalities to treat patients with methotrexate overdoses include AC and urinary alkalinization as well as glucarpidase (carboxypeptidase G) and extracorporeal removal ([Chap. 51](#)).

Intrathecal Methotrexate Overdose

Unintentional overdose with intrathecal methotrexate is potentially quite serious and is dose dependent.^{15,20} In these cases, IV leucovorin and not intrathecal leucovorin should be administered. Intrathecal leucovorin was considered a major factor in the death of a child given a slightly higher dose of intrathecal methotrexate than was prescribed.¹⁸ Not all intrathecal methotrexate overdoses require aggressive intervention, but consultation with experienced hematologists/oncologists and medical toxicologists is warranted (Special Considerations: SC3).¹⁷ Consideration should be given to providing intrathecal glucarpidase.

Methanol Toxicity

Either folic acid or leucovorin (folinic acid) should be administered parenterally at the first suspicion of methanol poisoning. Folic acid is most commonly used. No complications are reported with the use of 50 to 70 mg of IV folic acid every 4 hours for the first 24 hours in the treatment of methanol-poisoned patients.²⁸ The precise dosage necessary is unknown, but 1 to 2 mg/kg every 4 to 6 hours is probably sufficient. Folic acid should be continued until the methanol and formate are eliminated. Because the first dose is usually administered before hemodialysis, a second dose should be administered at the completion of hemodialysis because this highly water-soluble vitamin will have been eliminated.

FORMULATION AND ACQUISITION

Leucovorin (folinic acid) powder for injection is available in 50, 100, 200, and 350-mg vials. Each milligram of leucovorin contains 0.004 mEq of calcium. Reconstitution with sterile water for injection—5 mL to the 50 mg vial, 10 mL to the 100-mg vial, or 20 mL to the 200 mg vial—results in a final concentration of 10 mg/mL. Adding 17.5 mL of sterile water for injection to the 350-mg vial results in a final concentration of 20 mg/mL. These lyophilized products contain no preservatives. The only inactive ingredient is sodium chloride added to adjust tonicity. Reconstitute with Sterile Water for Injection, USP, when doses greater than 10 mg/m² are used and use immediately. Further dilute in 100 to 1000 mL of 0.9% sodium chloride or D₅W for infusion.²¹ Leucovorin is also available in a single-use vial as a solution for injection at a concentration of 10 mg/mL in a 50-mL vial. Because of the calcium content, the rate of IV administration should not be faster than 160 mg/min in adults.¹⁹ Leucovorin is also available orally in a variety of strengths, including 5, 10, 15, and 25 mg tablets.

Levoleucovorin⁶ lyophilized powder for injection is available in a single-use 50 mg vial containing the equivalent of 50 mg of levoleucovorin as the calcium pentahydrate salt and 50 mg of mannitol. Reconstitution with 5.3 mL of 0.9% sodium chloride injection, yields a concentration of 10 mg/mL.⁵ Levoleucovorin is also available as a sterile solution in a single-use 175 mg vial that contains 17.5 mL of sterile solution in which each milliliter contains levoleucovorin calcium pentahydrate equivalent to 10 mg of levoleucovorin and 8.3 mg of sodium chloride. Because of the calcium content, the rate of IV administration should not be faster than 160 mg/min (16 mL of reconstituted solution/min).⁶ Further dilution to concentrations of 0.5 mg/mL in 0.9% sodium chloride injection or 5% dextrose injection is acceptable but should be used within 4 hours when stored at room temperature.⁶

Folic acid is available parenterally in 10 mL multidose vials with 1.5% benzyl alcohol in concentrations of 5 or 10 mg/mL from a variety of manufacturers. After it has been opened, the vial must be kept refrigerated.

If administration to neonates is necessary, a benzyl alcohol–free preparation must be used because of the toxicity of benzyl alcohol in neonates ([Chap. 55](#)).

SUMMARY

- Leucovorin (folinic acid) is the primary antidote for a patient who receives an overdose of methotrexate.
- Leucovorin is the biologically active, reduced form of folic acid, the synthesis of which is prevented by methotrexate.
- Only leucovorin (folinic acid) is an acceptable antidote for a patient with methotrexate toxicity, but either folic acid or leucovorin is acceptable for a patient poisoned by methanol.
- After a methanol overdose, folic acid enhances the elimination of formate ([Table A10–2](#)).

TABLE A10–2. Rapid Calculations

1 mole = 1 g molecular weight

1 Molar = 1 mole/L

1×10^{-3} moles = 1 millimole = 1 mmol

1×10^{-6} moles = 1 micromole = 1 μ mol

1×10^{-9} moles = 1 nanomole = 1 nmol

1 mole of methotrexate weighs 455 Da; 1 mole methotrexate = 455 g

1 Molar methotrexate = 455 g/L = 455 mg/mL

1×10^{-8} Molar methotrexate = 455×10^{-8} g/L = 455×10.8 mg/mL = 455×10^{-5} μ g/mL = 455×10^{-2} ng/mL = 4.55 ng/mL

A11 ANTIDOTES IN DEPTH

Glucarpidase (Carboxypeptidase G₂)

Silas W. Smith

Glucarpidase (carboxypeptidase G₂, CPDG₂) is indicated for the management of methotrexate (MTX) toxicity. When given intravenously or intrathecally, it rapidly enzymatically inactivates MTX, folates and folate analogues. It does not substitute for and must be used in conjunction with leucovorin (Antidotes in Depth: A10). Leucovorin should not be administered within two hours before or after a dose of glucarpidase.

HISTORY

Soon after the description of the structure and synthesis of folate,⁶ a *Flavobacterium* species capable of removing the glutamate moiety of folate was discovered.³⁷ From 1955 to 1956, the inactivation of folate analogues (including by the chemotherapeutic aminopterin) was demonstrated in bacteria and yeasts.^{51,72} Purification of “carboxypeptidase G,” a pseudomonad-derived, zinc-dependent enzyme responsible for MTX cleavage, was reported in 1967.^{28,38} Other bacterial carboxypeptidases that differed in their substrate specificity and kinetics were isolated and purified in 1971 (*Pseudomonas stutzeri* carboxypeptidase G₁),⁴³ 1978 (*Flavobacterium* carboxypeptidase),⁵ and 1992 (*Pseudomonas* spp M-27 carboxypeptidase G₃).⁸⁰ By 1976, carboxypeptidase G₁ was scaled to pilot manufacturing production.¹⁸ Carboxypeptidase G₁ was initially explored as a chemotherapeutic to deprive growing tumors of folate.^{8,9,15,34} Human usage of CPDG₁ for this purpose was reported in 1974.⁹ The antidotal potential of carboxypeptidase was first suggested in 1972 when it was noted that carboxypeptidase G₁ rapidly decreased MTX concentrations and improved survival in mice injected with lethal MTX doses.¹⁶ CPDG₁ was subsequently used to selectively eliminate systemic MTX in patients treated with high dosages targeting central nervous system (CNS) malignancies.^{1,2} CPDG₁ was first used for rescue in a patient receiving MTX with kidney failure in 1978.³² Unfortunately, the enzyme source of CPDG₁ was then lost.^{4,82} The carboxypeptidase currently used in clinical practice (carboxypeptidase G₂) was cloned from *Pseudomonas* strain R16 and sequenced, characterized, and expressed in *Escherichia coli* in the early 1980s.^{46–48,63} The preliminary crystal structure was provided in 1991, with a complete characterization (at 2.5 Å) and description of the active site and biochemical mechanism of action in 1997.^{39,59,69} After the renewed availability of the recombinant CPDG₂ product, it underwent nonhuman primate testing for both intravenous (IV) and intrathecal (IT) rescue of MTX overdose.^{3,4} Reports of successful use in human IV and IT MTX overdose rapidly emerged.^{7,14,19,21,29,32,35,36,40,49,52,53,56,60,62,64,66,67,71,74,76–78,82} The US Food and Drug Administration designated glucarpidase an orphan product in 2003 and ultimately granted marketing approval in January 2012.¹³

PHARMACOLOGY

CHEMISTRY AND PREPARATION

Glucarpidase is produced by recombinant DNA technology. The enzyme cloned from *Pseudomonas* strain R16 is expressed in *E. coli* strain RV308.²⁴ The xenobiotic is manufactured in Belgium, and the final commercial product is filled, freeze dried, and packaged in the United States.^{24,31}

Mechanism of Action

Glucarpidase is a dimerized protein structure with two domains, a β-sheet interaction site and a zinc dependent catalytic domain.⁵⁹ The catalytic domain hydrolyzes C-terminal glutamate residues of folate and folate analogues such as MTX. Molecular modeling suggests that the two zinc (2+) ions bind a water molecule, promoting its polarization and nucleophilic

attack on the carbonyl group of the substrate (Fig. A11–1).⁷⁰ MTX and its metabolite 7-OH-MTX are thus split into inactive DAMPA (2,4-diamino-N¹⁰-methylpteroic acid) and OH-DAMPA plus glutamate.⁷⁹ DAMPA undergoes subsequent hepatic metabolism. Glucarpidase similarly inactivates leucovorin and folate by cleaving their terminal glutamate residues (Fig. A11–1).⁵

FIGURE A11–1. The catalytic domain of glucarpidase permits hydrolysis of the C-terminal glutamate residue of folate and folate analogues such as methotrexate (MTX) via hypothesized nucleophilic attack of a zinc bound water molecule.⁷⁰ (**A** and **B**) MTX and its metabolite 7-OH-MTX are split into inactive DAMPA (2,4-diamino-N¹⁰-methylpteroic acid) and OH-DAMPA plus glutamate. Glucarpidase similarly inactivates leucovorin (folinic acid) (**C**) and folate (**D**) by cleavage of

terminal glutamate residues.

Pharmacokinetics

In one study, 50 units/kg of glucarpidase was given IV to eight volunteer subjects with normal kidney function and four volunteers with impaired function (calculated creatinine clearance <30 mL/min; range, 9.8–27.4 mL/min).⁵⁷ Those with normal kidney function achieved a mean maximum serum concentration of glucarpidase of 3.1 µg/mL, with a mean half-life of 9.0 hours. These values were essentially unaffected in the setting of impaired glomerular filtration rate (GFR); therefore, renal dosing is not recommended.¹³ Glucarpidase restriction to the plasma compartment was implied by a volume of distribution of 3.6 L.⁵⁷ The large protein size (83 kDa dimer) of glucarpidase precludes traversing the blood brain barrier, crossing the cell membrane to act intracellularly, acting on MTX in the gut lumen, or treating MTX extravasation.^{1,16,19}

Pharmacodynamics

One unit of glucarpidase activity catalyzes the hydrolysis of 1 µmol of MTX per minute at 37°C.³ The mean enzymatic activity half-life of glucarpidase was 5.6 hours in normal volunteers and 8.2 hours in those with impaired GFR.⁵⁷ Its optimum activity pH is between 7.0 and 7.5, compatible with human physiology. After glucarpidase administration, a rapid decline of serum MTX concentrations by 71% to 99% occurred within minutes with the original Center for Applied Microbiology and Research (CAMR) product, with the concurrent appearance of inactive DAMPA in both serum and urine.^{14,36,62,64,73,74,76} DAMPA undergoes subsequent hepatic metabolism and renal elimination (~50%).⁷⁹ Commercial glucarpidase rapidly decreases serum MTX concentrations by greater than 97% within 15 minutes (Table A11–1).^{13,17,25,64} In one study, a reduction greater than 95% was sustained for up to 8 days in 20 of 22 patients.²⁵

ROLE IN METHOTREXATE TOXICITY

Patients receiving high-dose MTX therapy are routinely “rescued” with leucovorin (eg, 10 mg orally every 6 hours).⁸¹ Treatment nomograms and institutional algorithms recommend higher leucovorin doses when MTX concentrations are excessive or the elevation of the concentration is prolonged (Antidotes in Depth: A10).^{10,73,81} However, at MTX concentrations above 100 μmol/L (1×10^{-4} mol/L), data suggest that adequate leucovorin concentrations cannot be achieved for competitive and complete reversal of toxicity.^{14,36,41,58} Also, leucovorin administration provides 0.004 mEq of calcium per milligram of leucovorin and may be rarely associated with hypercalcemia in extremely high-dose therapy.⁸²

Glucarpidase is labeled for patients with serum MTX concentrations greater than 1 μmol/L in the setting of impaired kidney function (ie, an MTX concentration not within 2 standard deviations of the mean MTX excretion curve specific for the administered MTX dose).¹³ In the absence of an MTX concentration, significant mucositis, gastrointestinal (GI) distress, myelosuppression, hepatitis, or neurotoxicity should prompt consideration of glucarpidase in addition to aggressive leucovorin therapy while awaiting confirmation (off label).

Several efficacy and safety studies in both adults and children are summarized in Table A11–1. The CAMR product, used in several initial clinical trials,^{14,62,75} was not bioequivalent to the current commercial product.²⁵ Although no trial has yet demonstrated the superiority of glucarpidase as adjuvant therapy to leucovorin and supportive care alone, the pharmacodynamic efficacy is clear: baseline MTX concentration decreases by greater than 97%. Rapid and sustained clinically important reduction (RSCIR, [MTX] <1 μmol/L) occurred somewhat less frequently in 45%²⁵ and 67%¹⁷ of

patients. In exploratory analysis, patients with osteosarcoma—who received higher MTX doses (eg, 8–12 g/m²)—experienced less benefit with glucarpidase.²⁵ One analysis concluded that glucarpidase did not prevent fatal MTX toxicity in 3% of patients.¹³ However, data support the use of glucarpidase to treat those at risk of toxicity from MTX due to either persistently elevated MTX concentrations or kidney dysfunction.^{14,29,62,74} The use of glucarpidase to manage MTX toxicity has also permitted early resumption of MTX chemotherapy.^{7,17,21,67}

Intracellular MTX is polyglutamated, which hinders transmembrane transport and increases intracellular half-life. This MTX pool is inaccessible to glucarpidase (and hemodialysis) and can persist, causing cytotoxicity and a rebound in serum MTX concentrations for up to 85 hours after glucarpidase administration.^{27,62,75,77} Delaying glucarpidase more than 96 hours after MTX initiation, after intracellular MTX is established, is associated with failure to prevent significant MTX toxicity.^{62,75} This emphasizes the need for close monitoring of MTX concentrations and for early consideration for glucarpidase. Persistent intracellular MTX requires ongoing leucovorin therapy for 48 hours at the same leucovorin dose as that before glucarpidase and then repeated until the MTX concentration is below the leucovorin treatment threshold for a minimum of 3 days.¹³ Some authors continue leucovorin until the MTX concentration is less than 50 nanomol/L (0.05 μmol/L; 0.05×10^{-6} molar).⁷³

In the setting of oral MTX overdose, GI decontamination should be considered because glucarpidase has no intraluminal activity.

Because leucovorin is contraindicated for IT administration,^{23,33,68} IT glucarpidase provides an effective means to rapidly lower cerebrospinal fluid MTX concentrations in cases of overdose or prolonged persistence.^{3,52,77} The manufacturer is anticipated to pursue this indication under the “Animal Rule.”²⁵

Inadvertent or intentional MTX exposure^{50,65} is also an appropriate indication for glucarpidase, particularly before drug distribution. Additionally, glucarpidase has been proposed as an antidote for toxicity associated with pemetrexed (a folate antimetabolite).¹¹ In international patent applications, experiments demonstrated glucarpidase cleavage of pemetrexed and raltitrexed.^{44,45}

ADVERSE EFFECTS AND SAFETY ISSUES

Antidotal Compromise

The affinity of carboxypeptidase for MTX is 10 to 15 fold higher than for leucovorin; however, its affinity for the active metabolite of leucovorin, 5-methyltetrahydrofolate (5-mTHF) and folate are similar.^{5,22,63} Although racemic leucovorin is commonly prescribed, the active enantiomer is also commercially available. Because glucarpidase cleaves active levo-(6S)-leucovorin approximately 50% faster than inactive dextro-(6R)-leucovorin,³⁰ glucarpidase may compromise leucovorin rescue if both antidotes are administered contemporaneously. Fifteen minutes after administration of glucarpidase, median leucovorin and active 5-mTHF concentrations dropped by 8% and greater than 97%, respectively; the remaining leucovorin was likely the inactive d-isomer.^{73,75} Healthy volunteers provided leucovorin 2 hours after glucarpidase had their leucovorin concentrations decreased by 50%, and activated levo-5-mTHF was undetectable. When leucovorin therapy was delayed 26 hours after glucarpidase administration, enzymatic cleavage by glucarpidase still decreased leucovorin and 5-mTHF concentrations by 80% and 75%, respectively.²² In another study, when leucovorin was administered 2 hours after glucarpidase, maximum leucovorin concentration and area under the curve decreased by 54% and 33%, respectively; maximum (6S)-5-mTHF concentration and area under the curve decreased more significantly by 93% and 92%, respectively.²⁵ Thus, leucovorin should not be administered for at least 2 hours before or after glucarpidase is provided.

Immunogenicity

Initial studies reported adverse effects in four of nine patients treated with CPDG₁, including development of inactivating antibodies, “sensitization” to CPDG₁, and anaphylactoid reactions.^{1,2,9,32} In patients administered CPDG₂ fused to a murine single chain Fv antibody, 36% (11 of 30) developed anti-CPDG₂ antibodies, but no antimurine antibodies were detected.⁴² Studies using the noncommercial (CAMR) lot reported antiglucarpidase antibody (AGA) development in none of 28 patients⁷⁵ and in three of seven patients,⁶² respectively. In clinical trials using the commercial product, 15% (12 of 78) developed AGAs after a single glucarpidase dose, and 22% (4 of 18) developed AGAs after two doses.^{13,25} The current recombinant glucarpidase (CPDG₂) imparts a much lower incidence of adverse effects than the initial CPDG₁ enzyme, including paresthesias (2%), flushing (2%), nausea or vomiting (2%), hypotension (1%), headache (1%), and rash (0.3%).^{13,25} However, in intentional repeated dosing of glucarpidase with HDMTX, two of four patients experienced allergic reactions.²⁵

Although AGAs might decrease clinical efficacy or predispose to allergic reaction upon reexposure,^{2,4,22,62} many patients have been successfully treated with more than one dose of glucarpidase for persistently elevated MTX concentrations.^{14,19,36,53,56,62,66,78,82}

Other Considerations

Because “inactive” DAMPA has a pH-dependent urinary solubility eight to ten times less than MTX,^{30,74} alkalization and saline diuresis must be continued to prevent DAMPA precipitation and further renal compromise. Although the supplied product contains lactose and Tris-HCl with zinc buffer, lactose intolerant patients can receive glucarpidase. Previous concerns of allergic reactions to lactose-containing xenobiotics and patients with rare hereditary problems of fructose intolerance, galactose intolerance, galactosemia, or glucose–galactose malabsorption are unaddressed in prescribing guidelines.¹³

PREGNANCY AND LACTATION

Glucarpidase carries a pregnancy category C designation, although formal human and animal data are lacking. The excretion of glucarpidase in breast milk is unknown.

DOSING AND ADMINISTRATION

Glucarpidase is dosed in units per kilogram in both children and adults. After reconstituting each 1000 unit vial with 1 mL of sterile 0.9% sodium chloride, a single dose of 50 units/kg is administered immediately by bolus IV injection over 5 minutes. Although clinical studies permitted additional glucarpidase doses 24 to 48 hours later in cases of persistent MTX, repeat administration has not demonstrated significant efficacy.^{13,14,54,61} In cases of IT MTX overdose, a fixed dose of glucarpidase (2000 units) reconstituted in sterile 0.9% sodium chloride has been administered intrathecally (off label) over 5 minutes.^{52,77} A lack of compatibility studies precludes glucarpidase mixing with other xenobiotics.

Monitoring

False elevations of MTX concentrations are reported with all of the various immunoassay techniques after glucarpidase administration.^{21,30,36,56,78,82} The DAMPA product significantly cross-reacts with both MTX radioimmunoassay and competitive dihydrofolate reductase binding assays.²⁰ Both MTX metabolites (7-OH-MTX and DAMPA) appreciably interfere with fluorescence polarization immunoassay (FPIA) and enzyme multiplied immunoassay technique (EMIT) assays. For DAMPA, the cross-reactivity rates are 100% (EMIT) and 36% to 44% (FPIA).⁵⁵ 7-OH-MTX cross-reactivity using EMIT is 4% to 31%, and 0.6% to 3% with FPIA.^{26,55} Clinically, the concentrations of DAMPA detected are comparable to those of MTX after administration of CPDG₂.¹⁹ Thus, the use of high-performance liquid chromatography (HPLC) to determine actual MTX concentrations is mandated when glucarpidase is given.¹²

FORMULATION AND ACQUISITION

Branded glucarpidase (Voraxaze) is available in single use glass vials containing lyophilized glucarpidase (1000 units) with lactose monohydrate (10 mg), buffered to pH 6.5 to 8.0 with Tris-HCl (0.6 mg) and zinc acetate dihydrate (0.002 mg). It should be maintained at 36° to 46°F (2°–8°C) but not frozen. The manufacturer’s website details acquisition information for inside and outside of the United States (<http://www.btgplc.com/products/specialty-pharmaceuticals/voraxaze> and <http://www.btgplc.com/contact-us/contacts>, respectively).

SUMMARY

- Glucarpidase is a bacterially derived metalloenzyme used in the treatment of MTX toxicity. It cleaves MTX in the serum compartment to rapidly reduce serum MTX concentrations.
- Glucarpidase does not substitute for leucovorin, which must be continued to counteract persistent intracellular and CNS MTX.
- Do not administer leucovorin within two hours before or after a dose of glucarpidase to avoid the enzymatic destruction of folate and leucovorin.
- The measurement of MTX concentrations after glucarpidase administration will be unreliable unless HPLC is used.

SC3 SPECIAL CONSIDERATIONS

Intrathecal Administration of Xenobiotics

Rama B. Rao

Cerebrospinal fluid (CSF) is produced by the choroid plexus that lines the cerebral ventricles at a rate of 15 to 30 mL/h, or approximately 500 mL/d in adults.⁵⁰ CSF flows in a rostral to caudal direction and is resorbed through the arachnoid villi directly into the venous circulation. The estimated total volume of CSF is 130 to 150 mL in healthy adults and 35 mL in infants.^{50,66,89}

For more than 100 years, a variety of experimental and therapeutic xenobiotics have been delivered directly into the CSF^{57,116} (Table SC3–1). The most common current indications for intrathecal administration include analgesia, anesthesia, and treatment of spasticity or central nervous system (CNS) neoplasms. The clinical advantages of this route of administration include targeted delivery and lower medication dosages with fewer systemic effects. Medications are usually administered via a spinal needle or an indwelling intrathecal catheter. Catheters may be attached to either an external or subcutaneous pump. Less commonly, medications are administered into a reservoir of an intraventricular shunt. The distribution of intrathecal xenobiotics is determined by a variety of factors. Some authors speculate that the xenobiotic movement is often attributed to both diffusion and convection, and they suggest that the dilution of xenobiotics administered via a lumbar catheter is attributed to the outflow of CSF from the fourth ventricle.⁸² In a radiolabeled tracer study of five patients with lumbar catheters, individuals received the hydrophilic radiolabeled diethylene triamine pentaacetic acid (¹¹¹In-DTPA) intrathecally. Neuroimaging revealed a drop in concentration of the tracer as the fluid moved rostrally.⁵⁹ The steady-state lumbar to cervical concentration for hydrophilic xenobiotics is 4:1 with marked interindividual variability.⁸⁶ Depending on the lipophilicity, the xenobiotic reaches the brain within a few minutes to 1 hour. Patient position and interindividual variations in lumbosacral CSF volume may affect xenobiotic distribution and may account for the differences in the level of spinal anesthesia among patients administered the same local anesthetic dosages.⁴⁸ Baricity, which is the ratio of the specific gravity of the xenobiotic to the specific gravity of CSF at 98.6°F (37°C), is also a consequential variable. Hyperbaric xenobiotics typically distribute in accordance with gravitational forces.⁴⁸ However, in overdose or administration of xenobiotics unintended for intrathecal administration, distribution, resorption, and clinical effects may not follow predictable models.

TABLE SC3–1. Xenobiotics Administered Intrathecally^a

Analgesics/anesthetics
Anesthetics (local)
Ketamine ⁴⁶
Morphine ⁶³
Opioids ⁷⁰
Zinconitide ¹⁷
Antimicrobials
Amikacin ^{14, 26}
Amphotericin B
Arbekacin ³⁸
Cefotetan

Ceftriaxone²²
Gentamicin¹⁰¹
Levofloxacin¹⁴
Penicillin
Polymyxin E¹³
Vancomycin^{1, 71}
Antiinflammatory
Corticosteroids
Antispasmodic
Baclofen
Chemotherapeutics
Liposomal cytarabine¹⁶
Methotrexate
Vasoactive
Epinephrine
Papaverine¹⁰⁶
Phenylephrine
Other
Bethanecol⁸⁴
Clonidine²¹
Colistin¹¹²
Midazolam¹¹⁹
Neostigmine⁶³
Octreotide^{79, 85}
Somatostatin
Tetanus immunoglobulin²

^aFew of these xenobiotics are approved by the US Food and Drug Administration for intrathecal administration. Most were utilized in clinical trials or as rescue therapy for refractory central nervous system disorders.

Complications can occur from preparation and dosing errors or inadvertent penetration of the dura and admixture with the CSF during epidural anesthesia or analgesia.^{25,47,48} Medications intended for intrathecal delivery may be administered into the wrong port of a pump delivery system, resulting in a massive overdose (see Pump Malfunction and Errors, below). Another potentially fatal error involves inadvertent administration of the wrong medication into the CSF.⁵³ This error occurs with misidentification or mislabeling of medications during pharmacy preparation or at the bedside. For patients with indwelling devices, medications intended for intravenous delivery may be inadvertently connected to the intrathecal

catheter, which also currently operates the same via Luer lock system.

Several factors affect the clinical toxicity of intrathecal medication errors.¹¹⁷ The properties of the medication are important. Ionized xenobiotics are likely to disrupt normal neurotransmission and cause toxicity, as may hyperosmolar or lipophilic xenobiotics. The site of administration may be important as well. Patients administered the wrong xenobiotic into an Ommaya reservoir (an intraventricular catheter with a subcutaneous access port on the scalp) may suffer immediate alterations in mental status depending upon the xenobiotic administered. Although intrathecal administration of preservatives and excipients have been investigated in animal models, the characteristics of these adjuvants in medication errors is not likely to be of value in predicting clinical effect.⁴⁹

Patients may present with exaggerated symptoms, typically associated with the xenobiotic. For example, patients with intrathecal morphine overdose may present with symptoms of opioid toxicity.⁵⁵ Other manifestations of intrathecal errors, regardless of the xenobiotic, include pain and paresthesias, often ascending in nature; autonomic instability, especially with extremes of blood pressure; and hyperreflexic myoclonic spasms similar to those that occur in patients with tetanus. Seizures or a depressed level of consciousness may also occur. The time of onset of these life-threatening symptoms may be determined by the dose and characteristics of the xenobiotic. For example, a woman inadvertently administered intrathecal potassium chloride complained immediately of severe back pain.⁷² Myoclonic spasms, seizures, and coma followed, and the patient died within 3 hours despite a normal serum potassium concentration. Patients with inadvertent vincristine exposures may be asymptomatic for many hours and die within a few days to a few weeks. In another example, a patient with an inadvertent intrathecal administration of aminophylline immediately developed leg cramps. He recovered and was discharged, only to return 24 hours later for leg weakness progressing to irreversible paraplegia.⁷

XENOBIOTIC RECOVERY FROM CEREBROSPINAL FLUID

Once a medication delivery error is identified, rapid intervention is mandatory, especially for ionized xenobiotics, chemotherapeutics, or iodinated water-soluble contrast agents because these xenobiotics usually reach the brain within an hour. In cases in which outcome is uncertain or not previously described, the exposure should be treated as potentially fatal. Any existing access to the CSF, ideally in the lumbosacral area, should be maintained.¹¹⁰ Immediate withdrawal of CSF, in volumes as high as 75 mL in adults, is indicated. This can be replaced with isotonic solutions: lactated Ringer, 0.9% normal sodium chloride, or Plasma-Lyte, or a combination of these. Older cases utilized Elliot B solution. Some authors recommend the initial large volume removal be performed in 20 to 30 mL aliquots. For children, multiple aliquots of 5 to 10 mL can be removed and replaced with isotonic fluid. If the patient can tolerate an upright position, this may limit cephalad movement of xenobiotics, but positioning for any critical life support measures should take precedence.

Delays to initial CSF drainage should be minimized as the interval between the exposure and CSF drainage may also affect the total xenobiotic recovered (see below). In the interim, a neurosurgical consultation should be obtained to consider the placement of cerebral ventricular access for the performance of continuous CSF lavage. This procedure, also known as ventriculolumbar perfusion, involves continuous instillation of an isotonic solution into the cerebral ventricular system with CSF drainage through a lumbar site. Another intervention involves placement of an epidural catheter into the intrathecal space at a space above the lumbar drainage site. An isotonic solution can be perfused through the catheter and drained caudally. This serves as a readily available, rapid intervention for patients awaiting placement of an emergent ventriculostomy.^{74,103}

For ventriculolumbar perfusion, lavage flow rates can be as great as 150 mL/h. Fresh frozen plasma can be added to the lavage fluid after several hours to increase the CSF protein content. The ideal lavage fluid, protein components, and infusion rates are not known.⁴⁴ Some protocols previously utilized are listed in [Table SC3–2](#). Although artificial CSF formulations exist, their role in the treatment of such medication errors is not evaluated.⁷⁶

Table SC3–2. Inadvertent Intrathecal Exposures

<i>Xenobiotic</i>	<i>Age/Sex</i>	<i>Mechanism</i>	<i>Clinical Findings/Effects</i>	<i>Intervention</i>	<i>Outcome</i>
Amisophylline ¹	64/M	Medication error	Muscle cramps initially Paraplegia at 24 hours	Observation	Paraplegia Death in 2 years
Backfen ²⁸	8/M	Probable pump malfunction	Coma, vomiting, bradycardia	20 mL CSF removed at undetermined time	Survived
Bortezomib ^{33,34}	Unknown	Medication error			Three deaths
Bupivacaine ⁴	34/M	Inadvertent dural puncture	Hypotension Ascending paralysis at 10 minutes		Survived
Cefotetan ¹⁸	66/M	Catheter misconnection	Dyspnea, hypotension, myoclonic spasm, pain at 2 hours	10 mL CSF removed at 20 hours	Rhabdomyolysis Survived
Ceftriaxone ²⁷	74/F	Overdose	Bilateral lower extremity pain	240 mL CSF removed in 20 mL aliquots, with 0.9% NaCl replacement therapy Started at unknown time	Survived
Cytarabine ⁸	4/M	Overdose	Mydriasis, delayed onset, gait impairment, tremor	50 mL CSF removed in 5-mL aliquots, with 0.9% NaCl replacement therapy Started at 65 minutes Estimated 27%–36% cytarabine recovery	Died of unknown cause
Dactinomycin ⁹	5/F	Medication error	Hypotonia, fasciculations, hyperreflexia at 2 hours	50 mL CSF removed with 0.9% NaCl replacement at 1 hour, then VI perfusion started at 1.5 hours using 0.9% NaCl 100 mL/h with 2.5 mg/mL hydrocortisone for 26 hours Other adjuncts	Ascending paraplegia, obstructive hydrocephalus Survived
Doxorubicin ¹	12/F	Medication error	Fever, headache, vomiting at 12 hours, seizures, hydrocephalus	No attempt at removal	Survived without sequelae at 56 days
Doxorubicin ¹⁹	31/F	Medication error	Hypoesthesia, paraparesis, incontinence over 7 days, T8 sensory level, bowel, bladder incontinence, meningismus, adhesive arachnoiditis at 3 weeks	CSF exchange at 20 mL/h for 500 cm ³ per publication; methyl prednisolone 500 mg/d and immunoglobulin 22 g/d initiated at 1 week Treatment of arachnoiditis with VP shunt placement	Lower extremity weakness 3/5 at 8 months, eventual ambulation with resolution of incontinence at 14 months
Furosemide ¹⁸	36/M	Medication error	None	No attempt at removal	Survived
Gadolinium ⁷	64/M	Medication error: gadopentetate dimeglumine	Confusion, nausea, vomiting, ataxia, nystagmus, hallucinations, blurred vision, depressed mental status	Not described	Survived
Gallamine ¹²	48/M	Medication error	Hyperreflexic myoclonic spasm, onset 1 hour 45 minutes; fever, hypertension, tachycardia, miosis, coma at 3 hours	15 mL CSF drainage started at 6 hours	Survived
Iohexol ¹⁶	52/M	Dural perforation	ATCS at 30 minutes, coma, hypoxia, fever		Survived
Ionic contrast media cases ¹⁰	Various	Medication errors	ATCS starting at 30 minutes to 6 hours	Variable	3/7 patients died; fractures, rhabdomyolysis
Iopamidol ¹⁹	Various	Medication error	Cranial neuropathy		Survived
Iothalamate Contrast ¹⁰	48/M	Medication error	ATCS, opisthotonos	Sitting position, intubation 145 mL CSF removal in 10–20 mL aliquots Other adjuncts	Survived
Leucovorin ²⁷	11/M	Therapeutic error	Seizures		Died day 5
Lidocaine, epinephrine, fentanyl ¹⁰²					
Patient 1	28/F	Dural perforation	Hypotension, numbness at 5 minutes	20 mL CSF drained within 5 minutes 51% lidocaine recovery, 4% fentanyl recovery	Survived
Patient 2	68/F	Dural perforation	C ₁ –C ₅ sensory impairment at 18 minutes	30 mL CSF drained at 18 minutes 39% lidocaine recovery; 7% fentanyl recovery	Survived

Magnesium sulfate ⁶⁵	23/F	Medication error	Backache, lower extremity weakness, intact sensation, normotension	Fowler position	Recovery within 7 hours
Mercury ⁶⁶	69/F	Inadvertent (Mercurochrome) injection into CSF fistula	Local pain, nuchal rigidity, coma at 24 hours	Lumbar drain, parenteral chelation	Sensorimotor polyneuropathy Survived
Methotrexate ⁶⁷	2/F	Overdose	Headaches	Varied	Survived
Methotrexate ⁶⁸	34/M	Overdose	Confusion, seizures, ARDS, coma at 2 hours	200 mL CSF drained and replaced with 0.9% NaCl started at 6 hours in aliquots over 48 hours, then another 150 mL CSF exchange over 36 hours (patient also inappropriately received an intrathecal leucovorin)	Cognitive and motor deficits
Methotrexate ⁶⁹	9/M	Overdose	Lower extremity numbness, seizures, flaccid paralysis, cranial neuropathy, posturing	200 mL CSF drained in 30–40 mL aliquots, replacement with Eliott's B solution Started at 45 minutes 78% drug recovery	Died
Methotrexate series I ⁷⁰		Overdose			
Patient 1	12/M		Headache, vomiting at 45 minutes	30 mL CSF drained and replacement with 20 mL of Eliott's B solution started at 2 hours 28% drug recovery	Survived until relapse leukemia
Patient 2	4/M			10 mL CSF drained at 45 minutes 20% drug recovery	Survived
Methotrexate series II ⁷¹					
Patient 1	4/M			250 mL CSF drained in 20 mL aliquots, replacement with 0.9% NaCl Started at 5 hours	Survived
Patient 2	11/M			20 mL CSF withdrawn then 210 mL CSF drained in 5-mL aliquots, replacement with 0.9% NaCl Started at 3 hours 37% drug recovery	Survived
Methotrexate ⁷²	3/F	Medication error: 125 mg	Seizures at 3 hours	No CSF exchange; IV leucovorin rescue and dexamethasone	Survived
Methotrexate ⁷³	26/M	Medication error: 625 mg	Immediate pain in leg, followed by coma and flaccid paralysis, renal failure	70 mL CSF drained at 2 hours; VL perfusion with 240 mL 0.9% NaCl over 3 hours; intrathecal administration of 1000 units CPDG ₂ at 8.5 hours 32% recovery in initial drainage fluid 58% recovery from perfusion drainage	Survived
Methotrexate ⁷⁴	Case series n = 7	Medication errors: 155–600 mg	5/7 patients with seizures, some with headache, nausea, vomiting	Various interventions including VL perfusion started within 1 hour with 500 mL 0.9% NaCl over 4 hours	All survived
Methylene blue ⁷⁵	Case series: n = 14	Direct toxicity due to dye or pH: 10–100 mg	Pain headache, paralysis	Not described	11/14 residual paraplegia or weakness
Methylene blue ⁷⁶	39/M	6 mL 1% solution; as above	Vomiting, hypotension day 1; paralysis and urinary retention	Not described	Paraplegia and death at 5 years
Morphine ⁷⁷	45/F	Inadvertent filling wrong port of subcutaneous infusion pump; 450 mg	Seizures, hypertension, subarachnoid hemorrhage	12 mL CSF withdrawn, then 550 mL CSF drained at 10 mL/h by gravity over 2–3 days	Survived
Morphine ⁷⁸	81/M	Inadvertent: 5 mg	Coma at 4 hours	50 mL CSF drained over 6 minutes, replacement with 50 mL 0.9% NaCl	Survived
Morphine ⁷⁹	47/F	510 mg into wrong port of pump	Myoclonic spasms, coma, seizures, cranial neuropathy, hypertension then hypotension	No CSF interventions	Survived

Neostigmine ⁶¹	26/M	Medication error		None	Survived
PEG asparaginase ⁶²	12/M	Wrong route	None	None	Survived
Penicillin ⁶³	22/M	Dosing error into Ommaya reservoir	Coma, hyporeflexia, tonic-clonic seizures, absence seizures, hypotension at 30 minutes	10 mL CSF withdrawal, then VL CSF drainage; replacement with LR over 30 minutes	Survived
Potassium chloride ⁶⁴	42/F	Medication error during labor	Immediate cramps, pain, seizures, normal serum potassium	None	Maternal-fetal death at 3 hours
Tamadol ⁶⁵	75/F	Connection error	Diaphoresis, hypotension at 10 minutes; myoclonic spasms, opisthotonos	None	Fatal at 48 hours
Tranexamic acid ⁶⁶	49/F	Medication error, wrong route	Immediate back pain, hypertension; seizure at 2 minutes; ventricular fibrillation	None	Fatal at 1.5 hours
Vincristine ⁶⁷	5/F	Medication error: 0.9 mg	Headache at 10 hours, opisthotonos, nystagmus, flaccidity	None	Fatal on day 18
Vincristine ⁶⁸	2.5/F	Medication error: 3 mg	Opisthotonos day 2	200 mL CSF drainage in 10 mL aliquots; replacement with 0.9% NaCl	Fatal on day 3
Vincristine ⁶⁹	27/F	Medication error into Ommaya reservoir	Ascending paralysis	Detail limited: CNS "washout" FFP and "lactate solution" in undefined quantities; timing not described	Fatal on day 10
Vincristine ⁷⁰	16/M	Mislabeled	Ascending paralysis at 2 hours, fever, coma	None	Fatal
Vincristine ⁷¹	Adult	Medication error	Ascending paralysis	CSF drainage unreported quantity and replacement with LR immediately; VL perfusion 150 mL/h for >24 hours then 25 mL FFP in 1 L isotonic solution at 75 mL/h for undefined time 95% recovery of vincristine	Lower extremity neuropathy
Vincristine ⁷²	4/F	Medication error: 1.5 mg	Nystagmus, encephalopathy, ascending paralysis, transient improvement	Immediate drainage 18 mL CSF in 3 mL aliquots; replacement 0.9% NaCl; an additional 30–40 mL drained over 30 minutes, starting at 10 minutes; VL perfusion using Plasma-Lyte to replace 200 mL CSF over at unknown rate, then 6 mL FFP in 250 mL Plasma-Lyte at 50 mL/h for 4 hours	Fatal on day 13
Vincristine ⁷³	1.25/M	Medication error: 0.7 mg	Fetile and irritable at 10 hours then lower extremity pain, nuchal rigidity, opisthotonos, ileus, hypotonia at day 2; ascending paralysis, encephalopathy by day 5; respiratory arrest at day 7	Intrathecal corticosteroids at 10 hours	Death on day 75 (withdrawal of life support)
Vincristine ⁷⁴	7/F	Medication error: 0.5 mg	Ascending weakness, pain, paraplegia	Upright position; immediate drainage 75 mL CSF within 15 min, replaced with LR; VL perfusion started within 2 hours with 150 mL/h of LR for 10 hours, then FFP 15 mL in 1 L LR as irrigant at 55 mL/h for 24 hours Other efforts	Paraplegia, neurogenic bladder Survived
Vincristine ⁷⁵	12/F	Medication error: 2 mg	Asymptomatic for 48 hours, then ascending paralysis, hiccups, cranial neuropathy, coma	35 mL CSF drained at 30 min, then additional drainage of 15 mL CSF replaced with LR; VL perfusion at 3 hours using FFP 15 mL in 1 L LR for total drainage of 615 mL CSF over 10 hours 0.785 mg recovered	Death on day 83
Vincristine ⁷⁶	23/M	Medication error: 2 mg	Headache day 1; leg weakness day 2–3; ascending myeloencephalopathy with coma at day 10; seizures	Drainage of 100 mL CSF at 10 minutes, "large volume lumbar punctures" on day 2 and 3	Prolonged coma, death at 11 months
Vincristine series ⁷⁷		Medication error			
Patient 1	5/F		Ascending paralysis, opisthotonos, coma	Not described	Death on day 7
Patient 2	57/M		Ascending paralysis	"Flushing the subarachnoid space"	Death at 4 weeks

Vincristine [®]	3/M	Medication error	Day 1: leg pain Day 2: headache, nuchal rigidity Day 3: bladder dysfunction, fever, lower extremity paralysis, opisthotonos and coma	Not described	Death on day 6
Vincristine [®]	59/F	Medication error into Ommaya reservoir; 2 mg	Nausea, vomiting day 1; altered mental status, tremor, chills, hiccups, nystagmus, coma over 1 week	50 mL CSF drainage at 10 minutes followed by 75 mL CSF drainage at 30 minutes; VL perfusion with LR and FFP over 24 hours	Death on day 40
Vincristine [®]	10/F	Medication error	Asymptomatic for 6 days, then ascending paralysis with incontinence	Immediate drainage of CSF for 15 minutes; epidural catheter above the lumbar drainage site with lumbolumbar irrigation using 12.5 mL FFP in 500 mL LR with 96 mL drained; VL perfusion within 90 minutes for 24 hours	Survived with sensory-motor deficits of the extremities and urinary incontinence
Vincristine [®]	5.5	1.2 mg	Headache, vomiting and backache at 3 hours, nystagmus, extremity weakness at 72 hours, autonomic instability, hiccups, encephalopathy	Drainage of 20 mL CSF at 30 minutes, repeated on day 2, intrathecal corticosteroids, 23% recovery of dose	Death on day 12
Vincristine [®]	29/F	2 mg	Headache, ascending paraplegia, cranial neuropathy, coma	Intrathecal infusion 5 mL 0.9% NaCl with drainage of 10 mL CSF, positioned upright, additional 60 mL CSF drained at 3 hours	Death on day 14, pulmonary embolus at autopsy
Ziconotide series [®]		Overtitration of therapeutic dosage in each case		Stopped medication in each case	Improved days-weeks later
Patient 1	47/M		Nystagmus, auditory and visual hallucinations, dysmetria, ataxia		Retrograde amnesia
Patient 2	62/M for pain of multiple sclerosis		Agitation, disorientation, waxing and waning mental status, hallucinations, allodynia, bradycardia		Resolution with discontinuation of medication
Patient 3	45/M		Nausea, lightheadedness, nystagmus, bradycardia, agitation		Resolution with discontinuation

AICS = ascending tonic clonic syndrome (myoclonus, hyperreflexia on minimal stimulation, beginning in the lower extremities); CNS = central nervous system; CPG2 = calcitonin receptor-like receptor 2; CSF = cerebrospinal fluid; FFP = fresh frozen plasma; LR = lactated Ringer's solution; VL = ventriculolumbar; VP = ventriculoperitoneal.

Depending on the xenobiotic exposure, specific antidotes or rescue agents can be employed. With most intrathecal exposures, these rescue agents will be administered via oral, intramuscular, or intravenous routes. Extreme caution should be undertaken to avoid delivery of antidotes directly into the CSF, unless specific data support their use. Immediate, aggressive CSF removal and lavage resulted in nearly 95% recovery of vincristine in the lavage fluid of a patient with inadvertent exposure. Of the published cases in which xenobiotic recovery is reported, percentages relate to both the lavage method and quantity of CSF removed. For example, withdrawal of 10 mL of CSF 45 minutes after a methotrexate overdose in a 4 year-old patient recovered 20% of the initial dose.³ Withdrawal of 200 mL of CSF in aliquots 45 minutes after methotrexate overdose in a 9 year-old patient recovered 78% of the initial dose.³¹ The specific xenobiotic may affect recovery as well. For example, a patient underwent withdrawal of 30 mL of CSF 18 minutes after an overdose of simultaneously administered lidocaine, epinephrine, and fentanyl. Approximately 39% of lidocaine was recovered, whereas the recovery of fentanyl was only 7%.¹⁰²

SPECIFIC EXPOSURES

Ionic Contrast

Several xenobiotics have been utilized historically for contrast myelography. Many of these xenobiotics were abandoned because of their propensity to cause adhesive arachnoiditis chronic pain syndromes or other complications (Thorotrast). Low osmolar, nonionic contrast media are currently utilized, but unfortunately, other hyperosmolar ionic media are readily available in radiographic suites and sometimes inadvertently administered. Patients may develop cranial neuropathies.³⁶ Exposed patients become symptomatic within 30 minutes to 6 hours after administration, with hyperreflexia and myoclonic spasms following minimal stimulation.^{91,93,107} Clinical symptoms typically begin in the lower extremities and move in a cephalad direction, sometimes progressing to opisthotonos. This is likely due to alterations in inhibitory neurotransmission

occurring in patients with tetanus; this condition is called ascending tonic-clonic syndrome (ATCS). In one review, three of seven patients with ATCS died as a result of their exposures.⁹¹ Immediate large volume CSF drainage should be performed in 20 mL aliquots with isotonic fluid replacement. Ventriculolumbar perfusion should be considered in severe cases.

Chemotherapeutics

Methotrexate is administered intrathecally for the prevention and treatment of leukemic meningitis or other CNS neoplasms.⁹ Errors are generally dose related.^{3,29-31,44,51,62,90,108} In most reported cases, aggressive drainage of as great as 250 mL of CSF in aliquots with isotonic fluid replacement was utilized without ventriculolumbar perfusion. Experimental treatment of patients with intrathecal carboxypeptidase G₂ (CPDG₂) has been described without obvious adverse events.^{77,114} The patients underwent lumbar drainage followed by intrathecal CDPG₂. Drainage removed between 32% and 58% of the methotrexate, and the antidote reduced the methotrexate concentrations by 98%. The patients received 2000 units of intrathecal CDPG₂ in 12 mL of 0.9% sodium chloride solution over 5 minutes (Antidotes in Depth: A11).

Intrathecal leucovorin is absolutely contraindicated as its use results in fatalities. Following intrathecal methotrexate overdose, the intravenous administration of leucovorin is appropriate^{52,109} (Antidotes in Depth: A10).

Vincristine is typically administered intravenously and does not cross the blood brain barrier. There are no therapeutic indications for intrathecal vincristine, and such errors are almost invariably fatal.^{4-6,15,27,35,39,41,60} In most cases, the error is the result of confusion of either syringes or catheter access. As soon as the exposure is identified, immediate CSF drainage should be instituted, and rapid neurosurgical consultation should be obtained. The few known survivors with cognitive function underwent early neurosurgical intervention for ventriculolumbar perfusion.^{5,29,74,87,123} One of the patients had an epidural catheter placed intrathecally above the drainage site for lumbolumbar perfusion while awaiting ventriculostomy. This method of intrathecal perfusion should be considered in all patients with intrathecal vincristine exposures until definitive ventriculolumbar perfusion can be established. Ideally, tubing systems should be readily available to prevent intrathecal medication errors.^{80,105} Other rescue medications are discussed in Chaps. 36 and 52.

PUMP MALFUNCTIONS AND ERRORS

Some implantable pumps contain two access sites, one of which is contiguous with the intrathecal space and allows for CSF withdrawal or injection of nonionic contrast media for imaging. The other access site is a depot port that is intermittently filled with concentrated amounts of drug (usually an opioid analgesic or baclofen) to be delivered through a programmable pump. In some patients, a template must be placed on the skin overlying subcutaneous pumps to ascertain the proper medication port. Errors occur when a concentrated bolus is inadvertently injected into the wrong port resulting in a massive, sometimes fatal, overdose.^{53,118} Massive intrathecal morphine overdose can have severe rapid symptoms, including hypertensive crises. Either reaccessing the CSF port immediately or placing a spinal needle into the intrathecal space at another site is critical for the withdrawal of CSF. Large-volume drainage with isotonic fluid replacement is required, as well as other supportive measures such as intravenous naloxone if opioid toxicity is present. The patients usually require intubation and care in an intensive care unit. The clinical service that placed the pump should be consulted to assist in further CSF access and perform interrogation of the pump in cases where malfunction is suspected.²⁸ If the consultant is not readily available, emptying the depot port will automatically cause the pump motor to stop.

The other pump problem encountered is sudden, insufficient delivery of either baclofen or an opioid analgesic.⁸⁸ This may occur because of pump malfunction. Alternatively, the intrathecal catheter may kink, migrate, or become obstructed by an inflammatory mass.^{23,24,53,81} Patients with chronic use of baclofen or morphine may suffer severe withdrawal symptoms when intrathecal delivery is disrupted.¹¹³ Intrathecal doses are 100 to 1000 times more potent than the equivalent dose administered intravenously.⁵⁶ The patients may therefore require very high oral or intravenous doses to treat withdrawal until intrathecal delivery can be reestablished. The clinical service that implanted the pump should be consulted, and a thorough neurologic examination should be performed to evaluate for spinal cord compression symptoms.⁵³ An anteroposterior and lateral radiograph can be obtained to assess for kinking or fracture of the catheter.

ERROR PREVENTION

All intrathecal medication errors are preventable.⁴² Mechanisms for prevention are well described.^{32,69} They include trained pharmacists and administering physicians, specialized packaging and handling, use of minibags for intrathecal medications whenever feasible, preadministration of any intravenous medications, removal of all syringes and other medications from the area, and a checklist and time out with two persons reviewing all labels. More recently non-Luer lock systems are being explored to limit connection errors,⁷⁸ but these are predicted to be available in 2015. Any adopted system of prevention should include steps for intrathecal administration of required xenobiotics in all settings, including

treatment wards, outpatient clinics, radiology suites, and the operating room, as well as by all intrathecal routes such as implantable pumps, Ommaya reservoirs and lumbar or other access points.

SUMMARY

- Intrathecal medication errors can be life threatening.
- Errors may occur during preparation or administration.
- Rapid intervention with CSF drainage should be considered when a dosing or medication error occurs.
- More aggressive therapies may be required for chemotherapeutics, depending on the administered chemotherapeutics.

SC4 SPECIAL CONSIDERATIONS

Extravasation of Chemotherapeutics

Richard Y. Wang

Extravasation injuries are among the most consequential local toxic events. When certain chemotherapeutics leak into the perivascular space, significant necrosis of skin, muscles, and tendons can occur with resultant loss of limb or function. The initial manifestations may include swelling, pain, and a burning sensation that can last for hours. Days later, the area can become erythematous and indurated, followed by resolution or progression to ulceration and necrosis.³⁵ These early findings can be difficult to distinguish from other forms of local drug toxicity, such as irritation and hypersensitivity, which can result from the chemotherapeutic or its vehicle (ethanol, propylene glycol). For example, fluorouracil, carmustine, cisplatin, and dacarbazine are considered as local irritants. The local irritation and hypersensitivity manifestations are self-limiting and typified by an immediate onset of a burning sensation, pruritus, erythema, and a flare reaction of the vein being infused. Hypersensitivity reactions are reported with daunorubicin, doxorubicin, idarubicin, and mitoxantrone. Pretreatment with an antihistamine can prevent some of the hypersensitivity manifestations.⁴³ When a local reaction cannot be differentiated from an extravasation, it is prudent to presume extravasation has occurred and manage the situation accordingly.

The occurrence of extravasations appears to be about 50 times more frequent with inexperienced clinicians.¹⁹ Factors associated with extravasation injuries from peripheral intravenous lines include (a) poor vessel integrity and blood flow, such as those found in the elderly and in patients with numerous venipuncture attempts or who have received radiation therapy to the site; (b) limited venous and lymphatic drainage caused by either obstruction or surgical resection; and (c) the use of venous access overlying a joint, which increases the risk of dislodgments because of movement.^{20,35} Extravasation injuries from implanted ports in central venous vessels can occur from inadequate placement of the needle, needle dislodgement, damaged septum in the port, fibrin sheath formation around the catheter, perforation of the superior vena cava, and fracture of the catheter.³⁷ When extravasation from a central venous port is suspected and radiographic studies are not diagnostic, a computed tomography scan of the chest with contrast is necessary for evaluation.¹

The factors associated with a poor outcome from extravasation injuries include (a) areas of the body with little subcutaneous tissue, such as the dorsum of the hand, volar surface of the wrist, and the antecubital fossa, where healing is poor and vital structures are more likely to be involved; (b) increased concentrations of extravasate; (c) increased volume and duration of contact with tissue; and (d) the type of chemotherapeutic.^{35,36} Vesicants, such as doxorubicin, daunorubicin, dactinomycin, epirubicin, idarubicin, mechlorethamine, mitomycin, and the vinca alkaloids, result in more significant local tissue destruction than other types of chemotherapeutics, such as irritants. Mitomycin infusions can cause dermal ulcerations at venipuncture sites remote from the location of administration.³³ The anthracycline antibiotics are associated with a higher incidence of significant injuries and delayed healing, which can be a result of their slow release from bound tissue into surrounding viable tissue. Doxorubicin extravasation is associated with local tissue necrosis in approximately 25% of reported cases. The extravasation injuries from taxanes appear similar to the vesicants but are less severe in response and more delayed in presentation.^{3,34} Prevention is the best therapy for these injuries. Specialized nursing care and the use of indwelling central venous catheters limit the extent of these injuries.

MANAGEMENT

The treatment for extravasation injuries is controversial, varying from conservative care to early surgical débridement and the use of selective antidotes.³⁷ This uncertainty is a result of the limited number of clinical cases available for study and the discordance between animal studies and human experience. However, general and specific management guidelines for an extravasation and their theoretical foundations exist (Table SC4–1).^{6,9}

Once extravasation is suspected, the infusion should be immediately halted. A physician should be notified, and the chemotherapeutic, its concentration, and the approximate amount infused should be noted. The venous access should be maintained to permit aspiration of as much of the infusate as possible and administration of an antidote, if indicated. Injection of 0.9% sodium chloride into the catheter to dilute the extravasate can be beneficial.^{12,17,23,37} The intermittent local application of ice and elevation of the extremity should be done for 48 to 72 hours to limit further progression of the xenobiotic and the development of dependent edema. Cooling the affected area is believed to prevent cell injury by

reducing the amount of chemotherapeutic absorbed by the tissue and lowering the cellular metabolic rate.^{24,42} With just cold application and strict elevation, only 13 of 119 patients (11%) with mild extravasations required surgical intervention for their injuries.²⁷ In the past, heat was recommended to disperse the xenobiotic, but investigations with animals treated with intradermal doxorubicin demonstrated that this can increase the area of skin ulceration.^{11,27} However, dry, warm compresses are still recommended to promote the systemic uptake of the vinca alkaloids (vincristine and vinblastine) and etoposide.⁷ This is combined with the immediate and local infiltration with hyaluronidase to enhance absorption (Table SC4–1). Human recombinant hyaluronidase (Hyalenex) comes as 150 units/mL and it can be administered as five separate and equally spaced subcutaneous injections of 0.2 mL (30 units) using a 25-gauge or smaller needle at the leading edge of the infiltrate.^{13,14,18} Wounds that are either cancerous or infected should not be treated with hyaluronidase. Patients treated with hyaluronidase need to be monitored for allergic reactions, such as anaphylaxis, although the human recombinant form is less allergenic than animal-derived hyaluronidase.

The wound should be observed closely for the first 7 days and a surgeon consulted if either pain persists or evidence of ulceration appears.³⁵ However, in severe extravasations—where there is a high likelihood of necrosis because of the chemotherapeutic (doxorubicin), the volume or concentration, and any area in which there may be significant long-term morbidity (over joints)—early surgical consultation is recommended. If tissue ulceration occurs, initial management may be restricted to sterile dressings to prevent secondary infections. Once the area of necrotic skin can be clearly delineated from surviving tissue, surgical débridement can be beneficial to limit secondary infection. The use of intravenous fluorescein or other dye indicators can aid in identifying viable tissue.² The patient can require surgical reconstruction or skin grafts depending on the extent of the injury.

ANTIDOTES

Antidotal therapy should be considered when the extravasated xenobiotic is known to respond poorly to conservative care. The antidotal treatments can be categorized by their mechanism of action. Topical corticosteroids have been used to reduce the inflammatory response, including hypersensitivity reactions, from extravasated xenobiotics.^{23,44} However, this therapy remains a controversial practice for chemotherapeutics that are known to cause necrosis, such as doxorubicin and vinca alkaloids,^{4,19,28,40} because the initial injury is not attributed to the presence of inflammatory cells.⁸ Corticosteroids should not be added to doxorubicin infusions, because these drugs are chemically incompatible.³⁹ The administration of 5 mL of 8.4% sodium bicarbonate for extravasations with doxorubicin was advocated in 1980 because it could decrease the DNA binding of doxorubicin by altering the pH of the environment.⁵ However, this treatment is no longer routinely performed due to the intrinsic hyperosmolality of the bicarbonate solution, which can cause tissue necrosis.¹⁶ Sodium thiosulfate is recommended for mechlorethamine extravasations and is believed to inactivate the xenobiotic by reacting with the active ethylenimmonium ring.^{20,32} The site should be infiltrated with 2 mL of a sterile 4% (isotonic) sodium thiosulfate solution for each milligram of mechlorethamine, followed by intermittent ice compresses for 48 to 72 hours.⁶

Finally, there are antidotes, such as dimethyl sulfoxide (DMSO), that scavenge the free radicals that are believed to cause tissue damage from chemotherapeutics, such as doxorubicin. DMSO was shown to be beneficial for anthracycline extravasations in both animal and human clinical trials.^{7,11,28,32,38} DMSO was used at a concentration varying from 55% to 99% (w/v) and it was applied topically and then followed with intermittent cool compresses.^{7,15,28,31} Additional beneficial properties of DMSO are its antiinflammatory, analgesic, and vasodilatory effects, as well as its ability to promote systemic absorption of the chemotherapeutic at local sites.²⁹ However, the role for DMSO in the treatment of anthracycline extravasations has become secondary since dexrazoxane was approved by the FDA for use in the treatment of anthracycline extravasation in adults.²² Also, DMSO is not recommended in conjunction with dexrazoxane for the treatment of anthracycline extravasations. Dexrazoxane is believed to limit free radical cellular damage by chelating iron and directly acting as an antioxidant. The systemic administration of dexrazoxane limited anthracyclines-induced skin lesions in a murine model²⁵ and was used successfully in patients following doxorubicin^{10,26,41} and epirubicin^{21,25} extravasations. In two prospective, open-label, single-arm, multicenter clinical trials, the systemic administration of dexrazoxane within 6 hours of anthracycline extravasation resulted in the need for surgical resection of the wound site in only 1 of 54 (1.8%) patients.³⁰ Dexrazoxane was given to these patients over 3 days intravenously at a starting dose of 1000 mg/m², which was infused over 15 to 30 minutes at a site distant to that of the extravasation because of its irritating property. Cool compress at the site of the extravasation was discontinued for 15 minutes prior to therapy to promote the antidote's perfusion at the site. The dose of dexrazoxane (Table SC4–1) is decreased for patients with diminished renal function (creatinine clearance < 40 mL/min). Patients need to be monitored with serial CBCs and serum AST/ALTs because dexrazoxane can cause reversible bone marrow suppression and elevated liver enzymes. Additional clinical evidence needs to be gathered to better define the medical management of other chemotherapeutic extravasations. The overall incidence of extravasations with chemotherapeutics is likely small, the associated morbidity can be significant.

TABLE SC4–1. Management of Extravasational Injuries^{6,22}

	<i>Therapy</i>	<i>Purpose/Mechanism</i>
<i>General</i>		
	Stop infusion and maintain intravenous cannula at the site.	
	Aspirate extravasate from the site by accessing the original intravenous cannula.	Minimizes amount of chemotherapeutic localized at the site
	Irrigate subcutaneous tissue at the site with 0.9% sodium chloride by accessing the original intravenous cannula.	
	Apply dry cool compresses for 1 hour, every 8 hours for 3 days. ^a	Localizes area of involvement and diminishes cellular uptake of the chemotherapeutic
	Elevate extremity and administer analgesia.	Promotes drainage, prevents dependent edema, and provides comfort
<i>Chemotherapeutic Specific</i>		
Anthracyclines	Dexrazoxane 1000 mg/m ² , daily (max. 2000 mg per day), on days 1 and 2, and 500 mg/m ² on day 3 (max. 1000 mg); dose is decreased for patients with kidney disease	Limits free radical formation
Mechlorethamine	Sodium thiosulfate: Take 1.6 mL of 25% sodium thiosulfate and add to 8.4 mL of sterile water for injection to make a 4% solution Infiltrate the site of extravasation with 2 mL of 4% sodium thiosulfate per milligram of mechlorethamine in the extravasate.	Prevents tissue alkylation
Mitomycin	Dimethyl sulfoxide (DMSO): 55%–99% (w/v) applied topically and allowed to air dry	Free radical scavenger
Vinca alkaloids and epipodophyllotoxins	Hyaluronidase: inject, subcutaneously, 150 units/mL into the site as five separate and equally spaced injections of 0.2 mL using a 25 gauge or smaller needle at the leading edge of the infiltrate Dry warm compresses	Hyaluronic acid enhances systemic absorption Promotes systemic absorption

^aExcept for Vinca alkaloids and epipodophyllotoxins.

SUMMARY

- Prevention is the best form of therapy for these injuries.
- Immediately stop the infusion following a suspected extravasation.
- Aspirate, irrigate the site with 0.9% sodium chloride, apply dry cool compresses, elevate the extremity and administer

analgesia.

- Consider a specific antidote.

52 MISCELLANEOUS CHEMOTHERAPEUTICS

Richard Y. Wang

The anthracyclines,^{24,120} nitrogen mustards,^{1,38,55,60,90,130} and platinum-based complexes^{32,35,59,64,68,83,108,111,124} are discussed in this chapter because of their increased likelihood for overdose based on past reports and current clinical use.

ANTHRACYCLINES

Daunorubicin and doxorubicin share many common indications for cancer therapy, but they differ in that doxorubicin is used in solid tumors such as breast carcinoma, and daunorubicin is used in hematogenous malignancies, such as acute myelogenous leukemia and acute lymphocytic leukemia. The clinical toxicity of the older anthracyclines is limited by the use of less toxic structural analogs (eg, epirubicin, idarubicin) and liposome-encapsulated formulations (pegylated liposomal doxorubicin).

Pharmacology

The chemotherapeutics derived from the bacterium *Streptomyces* are dactinomycin, daunorubicin, doxorubicin, bleomycin, mitomycin, and plicamycin. Only plicamycin crosses the blood–brain barrier. Doxorubicin has a protein binding of 75% to 80%, a volume of distribution of 28.0 ± 3.3 L/kg, and a terminal elimination half-life of approximately 30 hours.⁴³ The liposome encapsulated formulation of doxorubicin has a prolonged terminal half-life of 50 hours because of a slower clearance compared with the nonencapsulated formulation. Doxorubicin and daunorubicin are both eliminated by the liver, and their dosages are decreased in patients with hepatic insufficiency. Delayed drug elimination contributes to increased area under the concentration versus time curve and peak concentration, both of which are associated with myelosuppression and cardiac toxicity, respectively.⁶⁶ The mechanism of therapeutic action of the anthracyclines is attributed to DNA intercalation¹⁰¹ and inactivation of topoisomerase II.¹¹⁷ These xenobiotics are metabolized to active metabolites, which have lesser degrees of activity than their parent compounds. The liposomal-encapsulated formulation of doxorubicin has limited selective activity at the tumor compared to nontumor sites in the body, such as the heart and bone marrow because of its particle size (100 Å).^{86,98} A typical dose schedule for daunorubicin is 30 to 60 mg/m² daily for 3 days; for doxorubicin, 45 to 60 mg/m² every 18 to 21 days; and for pegylated liposomal doxorubicin, 50 mg/m² every 28 days.

Pathophysiology

The red anthracycline antibiotics—dactinomycin and doxorubicin—are associated with cardiotoxicity, which limits their therapeutic use. The associated toxicity is caused by a different mechanism than the therapeutic effects.¹¹⁷ The purported mechanism of cardiac toxicity is from the formation of free radicals and impaired intracellular calcium.^{84,91} Doxorubicin and dactinomycin are quinone derivatives and can be reduced to free radicals. These metabolites are extremely cytotoxic through the promotion of lipid peroxidation in a manner similar to paraquat and bleomycin. The limited efficacy of free

radical scavengers (α -tocopherol, N-acetylcysteine) for anthracycline cardiotoxicity led to an understanding of the importance of iron as a cofactor for these free radical-producing reactions.⁸⁵ The anthracyclines have a high affinity for metal ions. Doxorubicin has an iron (Fe^{3+}) binding constant of 10^{41} , which is comparable to deferoxamine.⁴¹ The heart's increased susceptibility to free radicals is attributed to its lack of sufficient enzyme activity responsible for free radical scavenging.²⁹

Clinical Manifestations

The cardiotoxic manifestations can be divided into those occurring acutely or those of late onset. Acute toxicity is characterized by dysrhythmias, ST and T-wave changes on the electrocardiogram (ECG), diminished ejection fraction that usually resolves over 24 hours, or sudden death.^{12,113} Abnormal findings on ECG are present in 41% of patients receiving doxorubicin.^{103,113} These abnormalities are neither dose related nor associated with the development of cardiomyopathy. Acute pericarditis and myocarditis resulting in conduction defects and congestive heart failure (CHF) are also reported.¹³ Animal studies with doxorubicin demonstrate beneficial effects of adrenergic antagonists for toxicity because of elevated concentrations of catecholamines.¹³

Significant cardiotoxicity results from elevated peak serum concentrations and led to therapeutic decisions based on continuous or periodic infusion delivery. The anthracycline antibiotics can cause a congestive cardiomyopathy with systolic dysfunction that typically presents at 1 to 4 months after exposure.⁵³ The condition is irreversible and is associated with a 48% mortality.⁹⁴ This drug induced CHF is associated with pathognomonic changes on electron microscopy that can distinguish this type of cardiomyopathy from that of infectious and ischemic etiologies. These histologic changes include reduced numbers of myocardial fibrils, and mitochondrial and cellular degeneration.¹⁰ The incidence of late onset cardiotoxicity for doxorubicin is between 1% and 10% when the cumulative dose is less than 450 mg/m^2 , and this incidence becomes greater than 20% when more than 550 mg/m^2 (comparable to dactinomycin, 950 mg/m^2 , and epirubicin, 720 mg/m^2) is administered.^{79,127} Daunorubicin and mitoxantrone are associated with a 2% incidence at the cumulative doses of 600 mg/m^2 and 140 mg/m^2 , respectively.

The best way of monitoring cardiac function during therapy is to measure the left ventricular ejection fraction (LVEF) by radionuclide cineradiography or echocardiography.⁴ However, the radionuclide method is more sensitive to small decreases in the LVEF than the method using sonography.³⁶ Therapy should be discontinued when the ejection fraction falls below 50%. Two dimensional echocardiography can demonstrate left ventricular wall thickening and fractional shortening from anthracycline overexposure. Newer approaches used to determine early or subclinical signs of cardiac dysfunction include the evaluation of cardiac specific contractile protein, troponin, cardiac natriuretic peptide, and radionuclide tagged monoclonal antibody imaging.^{37,65,71}

Factors associated with an increased risk of cardiotoxicity include mediastinal irradiation, preexisting cardiac disease in children, age older than 70 years, and the concomitant use of cyclophosphamide, paclitaxel, and other anthracyclines.¹³ The recent therapeutic use of the monoclonal antibody to human epidermal growth factor receptor 2 (HER2), trastuzumab, with anthracyclines appears to enhance cardiac toxicity.²⁶ Children are at risk for developing increased left ventricular afterload from doxorubicin toxicity because of the ability of the drug to inhibit myocardial growth, which can lead to a disproportionate ratio of left ventricular wall thickness to left ventricular chamber size.⁶⁹ Fatalities are reported with minimum doses of 150 to 333 mg/m^2 and occur within 1 to 16 days following exposure.²⁴

Myelosuppression and mucositis from the use of the anthracyclines typically occur in 1 to 2 weeks.⁷ The white cells are affected more than either the red cells or platelets. Patients with diminished drug clearance due to hepatic failure are at risk for the development of these findings.

Mitoxantrone is less toxic than doxorubicin and daunorubicin. Major organs of toxicity remain the heart, bone marrow, and gut. Gastrointestinal effects are less severe and less frequent with mitoxantrone than with doxorubicin.¹¹⁰ Four cases of mitoxantrone overdose are reported in the literature.^{45,110} Common to these events is a 10-fold error in dosing (100 mg/m^2 instead of 10 mg/m^2), early onset of nausea with vomiting, and myelosuppression with fever. Acute decreased cardiac contractility was observed by echocardiography in an asymptomatic patient.⁴⁵ No patients developed dysrhythmias, congestive heart failure, ECG changes, or elevated creatine phosphokinase concentrations. Unfortunately, three patients developed fatal CHF from 1 to 4 months later.¹¹⁰

Management

Patients receiving anthracyclines require monitoring for cardiotoxicity and pancytopenia. A baseline chest radiograph, ECG, and echocardiography to determine LVEF (at rest and/or with stress) are necessary. Endomyocardial biopsy and cardiac catheterization can assist in distinguishing other causes of cardiac dysfunction. Left ventricular function is the best predictor for cardiomyopathy.^{34,104} A 10% absolute decrease in the LVEF or a decrease in LVEF of 50% from baseline is

an indication to discontinue anthracycline therapy.¹⁰⁴ Treatment is largely supportive and includes the use of dexrazoxane, which is a specific antidote for doxorubicin toxicity. Dexrazoxane is a cardioprotectant that limits the adverse cardiac effects of doxorubicin by chelating intracellular iron, which mediates the formation of free radical cellular damage.

In clinical trials, patients receiving dexrazoxane had smaller decreases in LVEF per dose of doxorubicin or epirubicin, had fewer histologic changes on cardiac biopsy, were better able to tolerate doxorubicin doses greater than 600 mg/m², and had a lower occurrence of CHF than did patients who were not pretreated with dexrazoxane.^{40,71,72,112,115,116,123} The current role of this chelator is to limit cardiotoxicity in patients receiving more than 300 mg/m² of doxorubicin.¹⁰⁶ It is administered 30 minutes before doxorubicin in a ratio not greater than 10:1 to limit dexrazoxane-induced granulocytopenia and thrombocytopenia.^{112,115,116} The early institution of β -adrenergic antagonists (carvedilol) or angiotensin-converting enzyme inhibitors can reduce cardiac dysfunction from anthracycline therapy, but they are less effective than dexrazoxane.^{42,58,70} Further investigations are required to determine the optimal use of dexrazoxane in patients with unintentional excessive exposures.

Enhanced Elimination

The anthracyclines are highly protein bound and have a large volume of distribution, which limits the use of hemodialysis. However, the early institution of hemoperfusion may enhance elimination. In an animal model, serum doxorubicin clearance could be enhanced up to 20 fold with hemoperfusion.¹²⁹ Factors determining this were duration of therapy, rate of flow, and the use of a 2% acrylic hydrogel coated cartridge. Three patients with a doxorubicin overdose were treated with hemoperfusion, one with an Amberlite cartridge, and all had a rapid reduction in their serum concentrations.²⁴ One survived a 10 fold error in dosing. In a patient with an intravenous mitoxantrone overdose of 98 mg, hemoperfusion was begun within hours, but in two sessions, only 0.287 and 0.236 mg of drug were removed.⁴⁵ The role of double-filtration plasmapheresis to enhance the elimination of liposomal encapsulated doxorubicin in the overdosed patient remains exploratory.⁹⁵

NITROGEN MUSTARDS

Mechlorethamine

Pharmacology

The nitrogen mustards include cyclophosphamide, ifosfamide, chlorambucil, mechlorethamine, and melphalan. Their indicated uses include immunosuppression (eg, controlling graft-versus-host rejection, collagen vascular diseases) and chemotherapy. The tumoricidal activity of these xenobiotics results from the formation of reactive intermediates that bind to chemotherapeutic moieties on DNA, which inactivates DNA synthesis. Mechlorethamine is the original compound from which all of the others were derived. It is highly reactive when it comes in contact with water and undergoes rapid chemical transformation. Local reactions caused by mechlorethamine spillage (eg, extravasation) include tissue injury and thrombophlebitis (Special Considerations: SC4). Nonenzymatic hydrolysis is the major route by which the nitrogen mustards are metabolized, thus accounting for their relatively short elimination half-lives (<3 hours).⁹ Unlike the other xenobiotics in this class, cyclophosphamide and ifosfamide are prodrugs and require cytochrome P450 (CYP2B6 and CYP3A4) activation to achieve their alkylating properties. The pharmacokinetic parameters estimated for ifosfamide are elimination half-life in blood, 4.5 hours (range, 3.4–6.1); volume of distribution, 0.56 L/kg (range, 0.29–0.82); clearance, 79 mL/min (range, 59–116); and protein binding, 20%.⁶⁷ Cyclophosphamide, ifosfamide, and chlorambucil have active metabolites, which prolong their alkylating activity after administration.⁵⁶

Clinical Manifestations

Chlorambucil and ifosfamide can cause altered mental status and myoclonic or tonic-clonic seizures from therapeutic use or from an overdose.^{15,16,38} Both chemotherapeutics undergo hepatic N-dechloroethylation to produce chloroacetaldehyde, which is a presumed nervous system toxin.⁶³ Encephalopathy occurs in 9% of patients receiving 5 g/m² of ifosfamide and is more frequent with oral than with intravenous (IV) administration because of the first-pass effect and increased chloroacetaldehyde production.⁷⁸ Seizures are more commonly associated with chlorambucil than other nitrogen mustards.

Acute overdoses reported from oral exposures range from 1.5 to 6.8 mg/kg (therapeutic is 0.1–0.2 mg/kg).^{5,16} The seizures occur within 6 hours, can appear as generalized tonic–clonic activity or staring spells, and last for up to 24 hours. However, in one instance in which therapeutic dosing was increased, seizures occurred 17 hours later. This delay can be attributed to a lower serum concentration, a slower time to peak than in the overdose setting, or accumulation of active metabolites. A similar reasoning could explain why a patient with a chronic overdose of 4.1 mg/kg over 5 days did not demonstrate central nervous system toxicity.³¹ Patients with increased likelihood for seizures include those with underlying seizure disorders or with nephrotic syndrome, which can alter pharmacokinetics.¹⁰¹ Myelosuppression can present as late as 41 days postexposure in patients with acute or chronic overdoses. Hematopoietic recovery is expected within one week of the nadir, and granulocyte colony stimulating factor treatment may be necessary.⁵⁵ Kidney failure from an acute overdose with ifosfamide is reversible following the immediate institution of hemodialysis.³⁸

Cyclophosphamide and its analog ifosfamide are metabolized to acrolein, which can result in cellular damage from the production of reactive oxygen and nitrogen species^{61,97} and cause hemorrhagic cystitis in approximately 5% to 10% of patients receiving therapy.^{15,23} The incidence of cystitis does not appear to be related to the total dose and administration route, age, or sex. The condition is usually self-limiting, although blood transfusions can be required. Water retention is typically observed in patients within 6 to 8 hours of receiving more than 50 mg/kg of cyclophosphamide. However, it can occur at a lower dose.^{27,52} This effect is attributed to the activity of the alkylating metabolite on the renal tubule or the release of endogenous vasopressin (syndrome of inappropriate antidiuretic hormone). The patient typically develops decreased urinary output, increased urine osmolality, and decreased serum osmolality, which is self-limiting and lasts for about 12 to 16 hours.

In overdose, cyclophosphamide can cause dysrhythmias, myocardial necrosis, hemorrhagic pericarditis, and death. ECG changes tend to occur at doses of 120 mg/kg, with heart failure and myocarditis at doses greater than 150 mg/kg.^{6,81} Diminished QRS voltage on the ECG is attributed to myocardial edema or hemorrhage. An ordering error led to the death of one patient and to irreversible cardiac damage in another patient from cyclophosphamide overdose. These two patients received 6520 mg daily for four consecutive days, as opposed to that amount divided over 4 days.¹⁰⁰ The onset of heart failure can be sudden, and patients older than 50 years of age and those with a history of cardiac dysfunction or prior treatment with anthracyclines are at greatest risk for cardiac toxicity.¹¹⁴

Management

Recommendations for patients with an acute oral chlorambucil overdose include routine gastrointestinal decontamination, 6 hour observation, determination of a complete blood count (CBC) and hepatic enzymes, and weekly CBCs for 4 weeks during follow-up.¹²² Ifosfamide-induced encephalopathy can be managed with the early administration of methylene blue (1–2 mg/kg IV as a 1% solution), although the mechanism by which methylene blue acts is unknown.^{63,132} Potential explanation for the role of methylene blue is as a free radical scavenger⁹³ and an inhibitor of guanylyl cyclase,^{76,102} which can limit the loss of cerebral vascular autoregulation and edema caused by nitric oxide synthesis and cyclic guanosine monophosphate production from the administration of ifosfamide^{61,102,118} (Antidotes in Depth: A42). Seizures are reported to be more effectively managed with benzodiazepines and barbiturates than with phenytoin.^{5,130}

When gross hematuria from cyclophosphamide or ifosfamide therapy persists, treatments can include electrocauterization, systemic vasopressin,⁹⁶ intravesical administration of silver nitrate,⁶⁹ formalin,^{39,107} prostaglandin F₂,¹⁰⁹ and hydrostatic pressure.⁵⁰ Strategies to preventive hematuria include adequate hydration for dilution effect, frequent bladder emptying, IV administration of 2-mercaptoethane sulfonate sodium (MESNA), and intravesical administration of N-acetylcysteine.¹⁵ The thiol group of N-acetylcysteine is believed to directly interact with acrolein and limit its irritating effect on the bladder epithelium. MESNA is believed to work by inactivating acrolein to an inert thioether.⁵¹ The IV dose of MESNA is 20% of the cyclophosphamide or ifosfamide amount (wt/wt) and administered during therapy and at 4 and 8 hours after chemotherapy. In overdose, MESNA does not protect patients from nephrotoxicity and hemodialysis is indicated. Hemodialysis effectively enhances the elimination of ifosfamide and its metabolites when instituted soon after exposure, and it is more effective than hemoperfusion (Adsorba 300 C, Gambro 300 g active carbon) in removing ifosfamide.³⁸

Patients with excessive exposures to cyclophosphamide require baseline ECGs and echocardiograms. IV fluid restriction, a cardiac inotrope (digoxin), and furosemide were successfully used to treat a patient with cyclophosphamide induced congestive cardiomyopathy.¹²⁶

PLATINUM-BASED COMPLEXES

Pharmacology

The cytotoxic effects of the platinum based complexes were first recognized in 1965. Of the many types developed, cisplatin, carboplatin, and oxaliplatin are of clinical utility.⁸² The latter two were designed to reduce the incidence of nephrotoxicity and to counter drug resistance to cisplatin. Cisplatin is an inorganic and carboplatin an organic compound. Similarities exist in their mechanism of toxicity, which is the binding of platinum to DNA to form inter- and intrastrand bonds, resulting in DNA dysfunction and strand breakage. These xenobiotics are eliminated from the body primarily in the urine. The amount eliminated at 24 hours is 25% for cisplatin and 90% for carboplatin. Patients with decreased creatinine clearance (<30 mL/min) have prolonged elimination half-lives of these complexes.³⁰

Pathophysiology

Kidney failure from renal tubular necrosis occurs with cisplatin in a dose-dependent manner. Upon entering the cell, cisplatin forms a cationic reactive complex, which covalently binds to DNA to disrupt replication and transcription, resulting in cell death. The formation of the hydrated platinum complex is favored by a low chloride concentration in the environment; thus, a sodium chloride infusion promotes the native state of cisplatin by preventing hypochloremia. The presence of α_1 -microglobulin, β_2 -microglobulin, retinol-binding protein, alanine aminopeptidase, or N-acetyl-D-glucosaminidase in the urine can be early indicators of renal tubular damage.^{25,46}

The sensory neuropathy associated with platinum containing chemotherapeutics that commonly are attributed to their accumulation and toxicity at the dorsal root ganglion, which is due to the water solubility and chemical reactivity of these xenobiotics.¹⁰⁵ Pathologic evaluation demonstrates increased platinum content at the dorsal root ganglion following cisplatin therapy, which suggests that the increased vascularity and fenestration of the endothelium at this tissue site contributes to the uptake of cisplatin.^{44,54}

Clinical Manifestations

The more common manifestations of toxicity with cisplatin with therapeutic dosing are kidney dysfunction, auditory impairment, and peripheral sensory neuropathy. The other chemotherapeutics that commonly cause a peripheral neuropathy are the Vinca alkaloids and the taxoids. Oxaliplatin induced neuropathy is triggered or enhanced by exposure to cold and can resolve over several months.³³ Myelosuppression is a dose-limiting factor for carboplatin and iproplatin, but it does not occur with cisplatin. At a carboplatin dose of 800 mg/m², 25% of patients develop bone marrow toxicity.⁸⁸ The marrow effects are delayed, with the nadir occurring 3 to 5 weeks after the start of therapy. Patients developing an anemia within the first week of cisplatin therapy should be evaluated for hemolysis.²⁰

The types of therapeutic dosing errors associated with cisplatin are frequency of administration (total dose versus divided dose), confusing cisplatin for carboplatin, and ordering an inappropriate dose.^{21,92} Manifestations in the overdose setting include neurologic, visual, hearing, bone marrow, pancreatic, and kidney disorders.¹⁰⁸ The most common kidney disorder is kidney failure, which is dose-related; it begins at 50 mg/m² and typically occurs at 1 to 2 weeks posttreatment. At this dose, approximately 30% of patients treated with cisplatin develop acute kidney injury (AKI) and a rise in serum blood urea nitrogen and creatinine concentration with subsequent electrolyte disorders, including hypomagnesemia, hypocalcemia, and hyponatremia.³² Hyponatremia is an uncommon finding with cisplatin exposure and is attributed to sodium-wasting nephropathy from renal tubular dysfunction (Chap. 19). At doses greater than 200 mg/m², seizures, encephalopathy, and irreversible peripheral sensory neuropathy are of concern.^{8,22,48,87-89} In addition, visual impairment, including temporary visual loss with permanent loss of color discrimination, can occur within the first week of therapy at this dose.^{19,75,128} Physical examination of the anterior chamber and fundus of the eye will be normal; however, an electroretinogram can demonstrate postphotoreceptor neural dysfunction.⁵⁹ Other possible ocular disorders are papilledema and retrobulbar neuritis. High-frequency (2000 Hz) hearing loss is evident 2 to 3 days after exposure to doses greater than 500 mg/m².¹⁷

Management

Renal protection and enhanced elimination of platinum are the goals in the initial management of a cisplatin overdose, followed by expectant management for myelosuppression and neurotoxicity. Hydration with 0.9% sodium chloride solution and an osmotic diuretic, such as mannitol, should be administered to achieve a high urine output (eg, 1–3 mL/kg/h) for 6 to

24 hours postexposure. Sodium chloride diuresis both promotes the inactive state of cisplatin and decreases the urine platinum concentration, which can limit nephrotoxicity.^{2,125} In the setting of nonoliguric AKI, careful hydration is recommended to maintain urinary output, because renal platinum excretion is directly related to urinary flow and independent of creatinine clearance.¹⁹ Kidney function can be monitored by determining the creatinine clearance or glomerular filtration rate.^{99,119}

Amifostine (Ethyol) and sodium thiosulfate are effective nephroprotectants. Amifostine is approved by the US Food and Drug Administration to prevent cisplatin induced nephrotoxicity, and additional benefits can include the limitation of myelosuppression, mucositis, and neurotoxicity.³ Unlike thiosulfate, amifostine is activated intracellularly by alkaline phosphatase to scavenge free radicals, regenerate glutathione, prevent cisplatin-DNA adduct formation, and facilitate DNA repair.⁶² The patient requires adequate hydration during amifostine infusion because hypotension can occur. Sodium thiosulfate is effective postexposure. Thiosulfate remains in the extracellular space to bind free platinum and limit cellular damage at the renal tubules. Little or no renal toxicity occurred in patients receiving as much as 270 mg/m² of cisplatin when thiosulfate was given as an IV bolus of 4 g/m² followed by infusion of 12 g/m² over 6 hours.^{47,90} In a 14 year-old patient with AKI from cisplatin, thiosulfate was continued at 2.7 g/m² a day until urinary platinum concentration was below 1 µg/mL.³² Thiosulfate can offer the additional benefit of limiting neurotoxicity^{74,121} and should be administered to all patients within 1 to 2 hours after a platinum-based complex chemotherapeutic overdose for it to be most effective (Antidotes in Depth: A40). N-Acetylcysteine and BNP7787 (2,2'-dithio-bis-ethanesulfonate) are under investigation as alternative rescue xenobiotics for cisplatin toxicity.^{11,28,80} BNP7787 also is under clinical investigation to limit peripheral neuropathy from paclitaxel therapy.⁷⁷

Hemodialysis is ineffective in patients with cisplatin overdoses, likely as a result of high protein binding.¹⁴ Plasmapheresis with plasma exchange was performed in five adults, and there was a decline in blood and plasma platinum concentrations with clinical improvement.^{18,19,49,57,131} In one incident, a patient received an overdose of 280 mg/m² and was plasmapheresed on day 12 of exposure.¹⁹ After three daily treatments, the serum platinum concentration decreased from 2900 to 200 ng/mL, and the patient had noticeable improvement in gastrointestinal and visual symptoms. On day 20, the serum platinum concentration rebounded to 700 ng/mL, and the symptoms worsened. Further plasmapheresis lowered the concentration to 290 ng/mL by day 27, and symptoms improved. In another event, a patient received 300 mg/m² of cisplatin and received four daily treatments of plasmapheresis starting on day 6 postexposure.⁵⁷ The serum platinum concentration declined from 2979 to 430 ng/mL, and the patient became more awake and less nauseated. On day 11, platinum concentrations rebounded to 834 ng/mL and fell to 279 ng/mL on reinstitution of plasmapheresis. The amount of platinum removed by three trials in this patient was approximately 4.6 mg. The author of the paper contends that plasmapheresis prevented the need for hemodialysis in kidney failure. Other reports have noted an improvement in patients' mental status and hearing loss following the decline in the serum cisplatin (platinum) concentration from plasmapheresis.^{18,49} Thus, plasmapheresis with plasma exchange should be immediately considered after a cisplatin overdose. Patients who remain symptomatic days later also may benefit.

SUMMARY

- Anthracyclines, nitrogen mustards, and the platinum based complexes are common chemotherapeutic overdoses.
- The primary clinical manifestations of toxicity for these xenobiotics include dilated cardiomyopathy (anthracyclines), encephalopathy and seizures (nitrogen mustards), and kidney failure (platinum based xenobiotics).
- The management for patients with these overdoses includes supportive care, enhanced elimination using plasmapheresis with plasma exchange for cisplatin, and antidotal therapy, such as dexrazoxane for anthracyclines and amifostine for platinum based complexes.
- Specialists in poison information and medical toxicologists must maintain a current level of understanding of these exposures so they can better assist their patients and provide consultation to other healthcare professionals.

53 ANTIDIABETICS AND HYPOGLYCEMICS

George M. Bosse

Glucose	
MW	= 180 Da
Normal fasting range (plasma)	= 60–100 mg/dL
	= 3.3–5.6 mmol/L

HISTORY AND EPIDEMIOLOGY

Insulin first became available for use in 1922 after Banting and Best successfully treated diabetic patients with pancreatic extracts.¹⁰ In an attempt to more closely simulate physiologic conditions, additional “designer” insulins with unique kinetic properties have been developed, including a rapid-acting basal insulin that mimics baseline insulin secretion known as lispro.^{67,140} Several oral delivery systems for insulin have been studied.⁹⁴ However, the development of an oral delivery system for use in humans has not been successful because of poor intestinal absorption and degradation of the oral form of insulin by digestive enzymes. Using zonula occludens toxin, modulation of intestinal tight junctions in animal models significantly increases enteral absorption of insulin.⁴² An inhaled form of insulin was withdrawn from the market due to poor sales and inability to demonstrate better glucose control than short-acting insulins.⁹⁰

The hypoglycemic activity of a sulfonamide derivative used for typhoid fever was noted during World War II.⁷⁶ This discovery was verified later in animals. The sulfonylureas in use today are chemical modifications of that original sulfonamide compound. In the mid-1960s, the first generation sulfonylureas were widely used. Newer second generation drugs differ primarily in their potency.

Although insulin is widely used for treating diabetes mellitus, oral hypoglycemic exposures are more commonly reported to poison centers than are insulin exposures, based on 15 years of data from 1996 to 2010 (Chap. 136). In an older review of 1418 medication-related cases of hypoglycemia, sulfonylureas (especially the long-acting chlorpropamide and glyburide) alone or with a second hypoglycemic accounted for the largest percentage of cases (63%).¹³⁰ Only 18 of the sulfonylurea cases in this series involved intentional overdose. However, hypoglycemia is reported in as many as 20% of patients using sulfonylureas.⁵⁹ In a study of 99,628 emergency hospitalizations for adverse drug events in adults older than 65 years of age, 14% were due to insulin and 11% were due to oral hypoglycemics. The majority (95%) of the hospitalizations related to these groups of endocrine agents were due to hypoglycemia.¹⁹ Other causes of hypoglycemia are listed in Table 53–1.

TABLE 53–1. Causes of Hypoglycemia

Artifactual	Medical Conditions	Neoplasms	Hypoglycin (Ackee)
Chronic myelogenous leukemia	Acquired immunodeficiency syndrome (AIDS)	Carcinomas (diverse extrapancreatic)	Indomethacin
Polycythemia vera	Alcoholism	Hematologic	Pentamidine
Endocrine Disorders	Anorexia nervosa	Insulinoma	Propoxyphene
Addison disease	Autoimmune disorders	Mesenchymal	Quinidine
Glucagon deficiency	Burns	Multiple endocrine adenopathy type 1 (Werner syndrome)	Quinine
Graves disease	Diarrhea (childhood)	Reactive Hypoglycemia	Ritodrine
Panhypopituitarism (Sheehan syndrome)	Leucine sensitivity	Xenobiotics	Salicylates
Hepatic Disease	Muscular activity (excessive)	β-Adrenergic antagonists	Streptozocin
Acute hepatic atrophy	Postgastric surgery (including gastric bypass)	Alloxan	Sulfonamides
Cirrhosis	Pregnancy	Antidiabetics	Vacor
Galactose or fructose intolerance	Protein-calorie malnutrition	Cibenzoline	Valproic acid
Glycogen storage disease	Rheumatoid arthritis	Disopyramide	Venlafaxine
Neoplasia	Septicemia	Ethanol	
Kidney Disease	Shock	Gatifloxacin	
Chronic hemodialysis	Systemic lupus erythematosus		
Chronic kidney insufficiency			

The biguanides metformin and phenformin were developed as derivatives of *Galega officinalis*, the French lilac, recognized in medieval Europe as a treatment for diabetes mellitus.⁸ Phenformin was used in the United States until 1977, when it was removed from the market because of its association with life-threatening metabolic acidosis with hyperlactatemia (64 cases/100,000 patient-years). However, phenformin still is available outside the United States.¹¹⁰

Development of the α -glucosidase inhibitors began in the 1960s when an α -amylase inhibitor was isolated from wheat flour.¹²⁶ Acarbose was discovered more than 10 years later and approved for use in the United States in 1995. Troglitazone and repaglinide were approved for use in the United States in 1997. The US Food and Drug Administration subsequently directed the manufacturer of troglitazone to withdraw the product from the US market in 2000 because of associated liver toxicity. Exenatide, a synthetic form of a compound found in the saliva of the Gila monster, is an incretin mimetic. Liraglutide is a synthetic analog of human incretin. Other newer xenobiotics include the gliptins and the amylin analog pramlintide.

PHARMACOLOGY

Insulin is synthesized as a precursor polypeptide in the β islet cells of the pancreas. Proteolytic processing results in the formation of proinsulin, which is cleaved, giving rise to C-peptide and insulin itself, a double-chain molecule containing 51 amino acid residues. Glucose concentration plays a major role in the regulation of insulin release.¹¹⁶ Glucose is phosphorylated after transport into the β islet cell of the pancreas. Further metabolism of glucose-6-phosphate results in the formation of ATP. ATP inhibition of the K^+ channel results in cell depolarization, inward calcium flux, and insulin release. After release, insulin binds to specific receptors on cell surfaces in insulin-sensitive tissues, particularly the hepatic, muscle, and fat cells. The action of insulin on these cells involves various phosphorylation and dephosphorylation reactions.

Figure 53–1 depicts the chemical structures of select antidiabetics. The sulfonylureas stimulate the β cells of the pancreas to release insulin and are often referred to as insulin secretagogues. They are ineffective in type 1 diabetes mellitus that results from islet cell destruction (Fig. 53–2). This stimulatory effect diminishes with chronic therapy. All the sulfonylureas bind to high-affinity receptor sensors on the pancreatic β cell membrane, resulting in closure of K^+ channels.^{40,47,48} Inhibition of potassium efflux mimics the effect of naturally elevated intracellular ATP and results in insulin release. High-affinity sulfonylurea receptors also present within pancreatic β cells are postulated to be either located on granular membranes or part of a regulatory exocytosis kinase. Binding to these receptors promotes exocytosis by direct interaction with secretory machinery not involving closure of the plasma membrane K^+ channels.^{40,47,48}

FIGURE 53–1. Chemical structures of representative oral antidiabetics. The glucagonlike peptide (GLP-1) analogs and amylin analogs are large polypeptides. Their structures are not shown here.

FIGURE 53–2. Under normal conditions, cells release insulin in response to elevation of intracellular ATP concentrations. Sulfonyleureas potentiate the effects of ATP at its “sensor” on the ligand gated K⁺ channels and prevent efflux of K⁺. The subsequent rise in intracellular potential opens voltage-gated Ca²⁺ channels, which increases intracellular calcium concentration through a series of phosphorylation reactions. The increase in intracellular calcium results in the release of insulin. Release of insulin is also caused by binding of sulfonyleureas to postulated receptor sites on regulatory exocytosis kinase and insulin granular membranes. Octreotide inhibits calcium entry through Ca²⁺ channel thereby inhibiting insulin release. GLUT = membrane bound glucose transporter.

The linkage of two guanidine molecules forms the biguanides. Metformin is an oral biguanide approved for treatment of type 2 diabetes mellitus. Its glucose-stabilizing effect is caused by several mechanisms, the most important of which appears to involve inhibition of gluconeogenesis and subsequent decreased hepatic glucose output. Enhanced peripheral glucose uptake also plays a significant role in maintaining euglycemia. The ability of metformin to lower blood glucose concentrations also results from decreased fatty acid oxidation and increased intestinal use of glucose.^{9,142} In skeletal muscle and adipose cells, metformin enhances activity and translocation of glucose transporters. Although the details are unclear, the mechanism by which this process occurs involves an interaction between metformin and tyrosine kinase on the intracellular portion of the insulin receptor. **Figure 53–3** depicts the mechanism of action of metformin.

FIGURE 53–3. Under normal conditions, insulin binding to its receptor on myocytes and adipocytes activates tyrosine kinase, resulting in phosphorylation and activation of the membrane-bound glucose transporter GLUT. Non–insulin dependent diabetes mellitus is causally associated with an increased activity of PC-1, a glycoprotein that inhibits tyrosine kinase activity and thus reduces myocyte and adipocyte glucose uptake. Metformin reduces PC-1 activity in these cells, enhancing peripheral glucose utilization. In addition, gluconeogenesis in hepatic cells is reduced through interference with pyruvate carboxylase, the enzyme responsible for conversion of pyruvate to oxaloacetate.

Acarbose and miglitol are oligosaccharides that inhibit α -glucosidase enzymes such as glucoamylase, sucrase, and maltase in the brush border of the small intestine. As a result, postprandial elevations in blood glucose concentrations are blunted.¹⁴⁹ Delayed gastric emptying may be another mechanism for the antihyperglycemic effect of these oligosaccharides.¹²⁰

Insulin resistance in patients with type 2 diabetes mellitus may occur because of secretion of biologically defective insulin molecules, circulating insulin antibodies, or target tissue defects in insulin action.¹⁰³ The thiazolidinedione derivatives decrease insulin resistance by potentiating insulin sensitivity in the liver, adipose tissue, and skeletal muscle. Uptake of glucose into adipose tissue and skeletal muscle is enhanced, while hepatic glucose production is reduced.^{17,58}

Repaglinide (Prandin) and nateglinide (Starlix) are oral representatives of the meglitinide class that also bind to K^+ channels on pancreatic cells, resulting in increased insulin secretion.¹²¹ Compared to the sulfonylureas, the hypoglycemic effects of the meglitinides are shorter in duration.

Exenatide and liraglutide are structurally similar to glucagonlike peptide-1 (GLP-1), an incretin that is released in response to an oral glucose load. GLP-1 enhances the release of insulin, delays gastric emptying, and reduces food intake. GLP-1 is metabolized very rapidly, rendering it therapeutically ineffective. Exenatide and liraglutide have much longer half-lives, rendering them useful in the treatment of type 2 diabetes mellitus.¹⁴⁶ Sitagliptin, saxagliptin, and linagliptin inhibit dipeptidyl peptidase-4 (DPP-4), the enzyme responsible for the inactivation of GLP-1.¹ Pramlintide is an amylin analog. Amylin is produced in the pancreatic β cell and acts in conjunction with insulin to inhibit gastric emptying, decrease postprandial glucagon secretion, and promote satiety.⁷⁷

PHARMACOKINETICS AND TOXICOKINETICS

Pharmacokinetic parameters of the hypoglycemics are given in [Tables 53–2 and 53–3](#). The onset and duration of action in

therapeutic doses vary considerably among preparations. Insulin overdose usually occurs after administration by the subcutaneous or intramuscular route. As might be predicted based on slow onset and prolonged duration of action of some of the preparations, insulin overdose may result in delayed and prolonged hypoglycemia. However, hypoglycemia may also occur with short acting forms because of some unusual toxicokinetic features. Some of these unpredicted responses may be caused by a depot effect following intramuscular or subcutaneous administration, and poor absorption may be further potentiated by the poor perfusion that can occur during periods of hypoglycemia.^{95,139} Further complicating the prediction of the clinical course is the delayed release of insulin from adipose tissue at the injection site(s). Because there are a finite number of insulin receptors, insulin overdoses of varying amounts probably are equivalent in terms of the degree of resultant hypoglycemia once receptor saturation occurs, but not in terms of its duration. A comparison can be made with the current treatment of diabetic ketoacidosis, in which lower doses of insulin are as effective as the higher doses used in the past.⁶⁶

Many of the sulfonylureas have long durations of action, which may explain the unusually long period of hypoglycemia that can occur in both therapeutic use and overdose. Second generation sulfonylureas (glimepiride, glipizide, glyburide) have half-lives that approach 24 hours and are characterized by substantial fecal excretion of the parent drug. These drugs frequently cause hypoglycemia (Table 53–2). Like insulin, the sulfonylureas may cause delayed onset of hypoglycemia following overdose.^{104,118} The reason for the potential delayed onset of effects with sulfonylureas cannot be simply explained by known kinetic principles but may be related to effective counterregulatory mechanisms that fail over time.

TABLE 53–2. Characteristics of Noninsulin Antidiabetics

<i>Xenobiotic</i>	<i>Duration of Action (hours)</i>	<i>Active Hepatic Metabolite</i>	<i>Active Urinary Excretory Product (% of Dose)</i>	<i>Fecal Excretion (% of Dose)</i>	<i>Likelihood of Hypoglycemia in Overdose</i>
I. Sulfonylureas					
First generation					
Acetohexamide (Dymelor)	12–18	Hydroxyhexamide (+++)	Hydroxyhexamide (65%) Acetohexamide (2%)	Negligible	Anticipate
Chlorpropamide (Diabinese)	24–72	2-Hydroxychlorpropamide (+) 3-Hydroxychlorpropamide (+)	Chlorpropamide (20%) 2-Hydroxychlorpropamide (55%) 3-Hydroxychlorpropamide (2%)	Negligible	Anticipate
Tolazamide (Tolinase)	16–24	Hydroxytolazamide (++)	Hydroxytolazamide (35%) Tolazamide (7%)	Negligible	Anticipate
Tolbutamide (Orinase)	6–12	Hydroxytolbutamide (+)	Hydroxytolbutamide (30%) Tolbutamide (2%)	Negligible	Anticipate
Second generation					
Glimepiride (Amaryl)	24	Cyclohexylhydroxy ethyl derivative (++)	Cyclohexylhydroxy methyl derivative (63%)	15%	Anticipate
Glipizide (Glucotrol, Glucotrol XL)	16–24	None	Glipizide (3%)	12%	Anticipate
Glyburide (Micronase, Glynase, DiaBeta)	18–24	4-Hydroxyglyburide (++)	4-Hydroxyglyburide (36%) Glyburide (3%)	50%	Anticipate
II. Biguanides					
Metformin (Glucophage, Glucophage XR)	1.3–4.5	None	Metformin (90%)	Negligible	Unlikely
Phenformin	6–8	None	Phenformin (66%)	Negligible	Unlikely
III. α-Glucosidase Inhibitors					
Acarbose (Precose)	2	None	4-Methyl pyrogallol derivative (<2%)	None	Unlikely
Miglitol (Glyset)	2	None	100%	None	Unlikely
IV. Thiazolidinedione Derivatives					
Pioglitazone (Actos)	16–24	Hydroxy derivative++ Keto derivative++	<15%–30%	70%	Unlikely
Rosiglitazone (Avandia)	12–24	None	None	23%	Unlikely
V. Meglitinides					
Nateglinide (Starlix)	2–4	Isoprene derivative (++) Hydroxylation metabolites (+)	– 16% as parent	10%	Anticipate
Repaglinide (Prandin)	1–3	None	None	90%	Anticipate
VI. GLP-1 Analogs					
Exenatide (Byetta, Bydureon)	6–8	None	None	Negligible	Unlikely
Liraglutide (Victoza)	24	None	None	5%	Unlikely
VII. Glitins					
Sitagliptin (Januvia)	24	None	Sitagliptin (70%–80%)	16%–20%	Unlikely
Saxagliptin (Onglyza)	24	5-hydroxy derivative (++)	Saxagliptin (24%) 5-hydroxy (36%)	22%	Unlikely
Linagliptin (Tradjenta)	24	None	Linagliptin (5%)	80%	Unlikely
VIII. Amylin Analog					
Pramlintide (Symlin)	3	None	None	Negligible	Unlikely

Metformin metabolism is negligible, and the majority of an absorbed dose is actively secreted in the urine unchanged. Plasma protein binding is also negligible.⁹ Repaglinide and nateglinide are prandial glucose regulators characterized by rapid onset and short duration of action. Overdose experience and toxicokinetic data for repaglinide are lacking. It is not clear whether hypoglycemia would be prolonged or delayed in onset following overdose. In one case of nateglinide overdose, hypoglycemia occurred early and was short lived.⁹⁶ Exenatide and liraglutide are available only for parenteral

(subcutaneous) injection. Sitagliptin, saxagliptin, and linagliptin have long half-lives and cause pronounced inhibition of DPP-4, resulting in a long duration of action (approximately 24 hours) after therapeutic doses.⁷⁴ Pramlintide is available only for parenteral (subcutaneous) injection and has a half-life of approximately 40 minutes when used in therapeutic doses.²⁶

PATHOPHYSIOLOGY OF HYPOGLYCEMIA

To varying degrees, the antidiabetics may all produce a nearly identical clinical condition of hypoglycemia. The etiologies of hypoglycemia are divided into three general categories⁴⁴: physiologic or pathophysiologic conditions (Table 53–1), direct effects of various hypoglycemics (Tables 53–2 and 53–3), and potentiation of hypoglycemics by interactions with other xenobiotics (Table 53–4).

TABLE 53–3. Characteristics of Various Forms of Insulin

<i>Insulin</i>	<i>Onset of Action (hours)</i>	<i>Duration of Action (hours)</i>	<i>Peak Glycemic Response (hours)</i>
Rapid Acting			
Aspart (NovoLog)	0.25	3–5	0.75–1.5
Glulisine (Apidra)	0.5	<5	1.5–2
Lispro (Humalog)	0.25–0.5	<5	0.5–2.5
Short Acting			
Regular (Humulin-R, Novolin-R)	0.5–1	5–8	2.5–5
Intermediate Acting			
Lente (Humulin-L, Novolin-L)	1–3	18–24	6–14
NPH (Humulin-N, Novolin-N)	1–2	18–24	6–14
Long Acting			
Detemir (Levemir)	1.5	24	No true peak
Glargine (Lantus)	1.1	24	No true peak
Ultralente (Humulin-U)	4–6	20–36	8–20

TABLE 53–4. Xenobiotics Known to React with Hypoglycemics Resulting in Hypoglycemia

- β-Adrenergic antagonists
- Angiotensin-converting enzyme (ACE) inhibitors
- Allopurinol
- Anabolic steroids
- Chloramphenicol
- Clofibrate
- Disopyramide
- Ethanol
- Fluoroquinolones
- Haloperidol
- Methotrexate

Monoamine oxidase inhibitors

Pentamidine

Phenylbutazone

Probenecid

Quinine

Salicylates

Sulfonamide

Trimethoprim-sulfamethoxazole

Warfarin

Hypoglycemia usually results in decreased insulin secretion, with production of alternate fuels, particularly ketones. Ketone production occurs as a result of fatty acid metabolism.⁷⁰ Nonketotic hypoglycemia can occur in a hyperinsulinemic state such as insulinoma.¹⁰⁶

Central nervous system (CNS) symptoms predominate in hypoglycemia because the brain relies almost entirely on glucose as an energy source. However, during prolonged starvation, the brain can utilize ketones derived from free fatty acids. In contrast to the brain, other major organs such as the heart, liver, and skeletal muscle often function during hypoglycemia because they can use various fuel sources, particularly free fatty acids.¹³²

Emphasis on tighter glucose control as a means of preventing microvascular effects carries with it an increased risk for hypoglycemia.^{32,33} Regulation of glucose control to near-normal glucose concentrations, the characteristics of each individual's awareness of hypoglycemia, and the individual counterregulatory mechanisms define the frequency and intensity of hypoglycemia.¹³¹ The Diabetic Control and Complications Trial research group reported 62 episodes of blood glucose concentration less than 50 mg/dL with CNS manifestations requiring assistance for every 100 patient-years in patients undergoing an intensive insulin therapy regimen. This was in comparison to a conventional therapy group, which had 19 such episodes per 100 patient-years.^{32,33} The intensive therapy group received three or more insulin injections per day or used a pump in an effort to achieve a glucose concentration as close to normal as possible, whereas the conventional therapy group received one or two daily insulin injections.

There has also been a recent emphasis in tighter control of glucose in critically ill patients, even in the absence of known diabetes mellitus. Hyperglycemia occurs in critically ill patients due to several mechanisms and is associated with increased mortality in patients with a variety of medical and surgical diagnoses.⁶⁸ In a study of critically ill surgical patients, tight control of glucose was associated with decreased morbidity and mortality.¹⁵¹ However, such benefits in other studies are not always clearly replicated, and significant hypoglycemia is reported.^{41,150}

The autonomic nervous system regulates glucagon and insulin secretion, glycogenolysis, lipolysis, and gluconeogenesis. β -Adrenergic antagonists affect all of these mechanisms and can result in hypoglycemia. In the presence of kidney failure, β -adrenergic antagonist-induced hypoglycemia is a particular risk⁵¹ secondary to increased insulin half-life and reduced renal gluconeogenesis.¹⁰⁷ In addition, the clinical presentation of hypoglycemia may be muted when β -adrenergic antagonists are present because the expected autonomic responses of tachycardia, diaphoresis, and anxiety may not occur. Although this is assumed to be true, an adverse effect on hypoglycemic awareness could not be demonstrated in healthy volunteers given metoprolol, atenolol, and propranolol.⁶⁴

The concept of hypoglycemia-associated autonomic failure in diabetes mellitus is well described.³⁰ Recurrent episodes of hypoglycemia result in autonomic failure by causing defective glucose counterregulation and possibly hypoglycemic awareness. As glucose concentrations fall, normal sensing mechanisms result in decreased insulin secretion and increased glucagon and epinephrine secretion. These counterregulatory defenses against hypoglycemia are defective in most people with type 1 diabetes mellitus and in many with type II diabetes mellitus.

Although various nonantidiabetic xenobiotics can cause hypoglycemia (Table 53–1), salicylates and ethanol are particularly notable for their unintended hypoglycemic effects. The mechanism of ethanol-induced hypoglycemia is discussed in Chap. 80. Salicylate inhibition of prostaglandin synthesis in the β cell of the pancreas is postulated to result in enhanced insulin secretion.¹¹ Salicylates may also cause hypoglycemia by poorly defined mechanisms that do not involve enhanced insulin secretion.

CLINICAL MANIFESTATIONS

Hypoglycemia and its secondary effects on the CNS (neuroglycopenia) are the most common adverse effects related to insulin and the sulfonylureas. It is essential to remember that hypoglycemia is primarily a clinical, not a numerical, disorder. Clinical hypoglycemia is the failure to maintain a plasma glucose concentration that prevents signs or symptoms of glucose deficiency. The clinical presentations of patients with hypoglycemia are extremely variable. Hypoglycemia must be considered to be the etiology of any neuropsychiatric abnormality, whether persistent or transient, focal or generalized. The cerebral cortex usually is most severely affected. These findings are categorized below¹¹⁵:

- Delirium with subdued, confused, or manic behavior.
- Coma with multifocal brainstem abnormalities, including decerebrate spasms and respiratory abnormalities, with preservation of the oculocephalic (doll's eyes), oculovestibular (cold-caloric), and pupillary responses.
- Focal neurologic deficits simulating a cerebrovascular accident (CVA) with or without the presence of coma. During a 12-month study period, 3 of 125 (2.4%) hypoglycemic patients presented with hemiplegia.⁸³ There are numerous reports^{4,135} and series^{128,148} of patients with focal neurologic deficits.
- Solitary or multiple seizures.

These neuropsychiatric symptoms are usually reversible if the hypoglycemia is corrected promptly. The morbidity resulting from undiagnosed hypoglycemia is related partly to the etiology and partly to the duration and severity of the hypoglycemia. Because the etiologies of hypoglycemia encompass both severe diseases such as fulminant hepatic failure and benign problems such as a missed meal by an insulin-requiring diabetic, the literature with regard to outcome is confusing. Although a study of 125 emergency department (ED) cases of symptomatic hypoglycemia reported an 11% mortality rate,⁸³ only one death (0.8%) was attributed directly to hypoglycemia. In that same study, nine patients (7.2%) presented with seizures (focal in one case), three patients (2.4%) presented with hemiparesis, and four survivors (3.2%) suffered residual neurologic deficits. In one tertiary care medical center, 1.2% of all admitted patients had hypoglycemia (defined as a glucose concentration less than 50 mg/dL). The overall mortality was 27% for this group of 94 patients.⁴⁴ The longer and more profound the hypoglycemic episode, the more likely permanent CNS damage will occur.⁷

No absolute criteria available from the physical examination or history distinguish one form of metabolic coma from another. Moreover, the findings classically associated with hypoglycemia, such as tremor, sweating, tachycardia, confusion, coma, and seizures, frequently may not occur.⁵⁶ The glycemic threshold is the glucose concentration below which clinical manifestations develop, a threshold that is host variable. In one study, the mean glycemic threshold for hypoglycemic symptoms was 78 mg/dL in patients with poorly controlled type 1 diabetes compared to 53 mg/dL in those without the disease.¹⁵

Patients with well-controlled type 1 diabetes may be unaware of hypoglycemia. It appears that even in the presence of numerical hypoglycemia, diabetics with near-normal glycosylated hemoglobin concentrations maintain near-normal glucose uptake by the brain, thereby preserving cerebral metabolism and limiting the response of counterregulatory hormones. The result of this limited response is unawareness of hypoglycemia.^{14,15} A threshold is likely achieved below which the glucose concentration is inadequate, but this may be a concentration so close to that causing serious neuroglycopenia that patients have limited opportunity for corrective action.¹⁴ Hypoglycemia unawareness is most likely in diabetics with chronic use of hypoglycemics because of hypoglycemia-associated autonomic failure.³⁰ Acute ingestion of hypoglycemics in nondiabetic patients likely would cause more classic signs and symptoms.

Sinus tachycardia, atrial fibrillation, and ventricular premature contractions are the most common dysrhythmias associated with hypoglycemia.^{75,102} An outpouring of catecholamines, hypoglycemia itself, transient electrolyte abnormalities, and underlying heart disease appear to be the most likely etiologies. Based on their mechanisms of action, both insulin and the sulfonylureas are expected to promote the shift of potassium into cells, and hypokalemia after insulin overdose is well documented.^{6,139} Other cardiovascular manifestations include angina and ischemia, which rarely may be the sole manifestations of hypoglycemia.³⁸ Both are directly related to hypoglycemia.^{12,112} Increased release of catecholamines during hypoglycemia increases myocardial oxygen demand and may decrease supply by causing coronary vasoconstriction.

Hypothermia may occur in hypoglycemic patients.^{45,63,141} If present, hypothermia usually is mild (90°–95°F {32°–35°C}), unless coexisting conditions such as environmental exposure, infection, head injury, or hypothyroidism are present. In a study comparing two groups of patients with depressed mental status, hypothermia was almost exclusively limited to the hypoglycemic patients; of these patients, 53% with demonstrated hypoglycemia showed hypothermia.¹⁴¹ The central hypothalamic response to hypoglycemia stimulated by the sympathetic nervous system may actually “overshoot” normal temperatures, resulting in hyperthermia following recovery.²⁷

Besides decreasing glucose concentrations, the hypoglycemics can produce a number of adverse effects, both in overdose and in therapeutic doses. Older sulfonylureas, predominantly chlorpropamide, cause a syndrome of inappropriate antidiuretic hormone secretion⁶¹ and disulfiram-ethanol reactions.¹¹³ These adverse effects are exceedingly uncommon with the newer second-generation sulfonylureas.

Hypoglycemia may not occur until 18 hours after lente insulin overdose,⁹⁵ may persist for up to 53 hours after subcutaneous insulin glargine overdose,¹⁸ and may persist up to 6 days after ultralente insulin overdose.⁸⁴ Death after insulin overdose cannot be correlated directly with either the dose or preparation. Some patients have died with doses estimated in the hundreds of units, whereas others have survived doses in the thousands of units.¹²⁷ Mortality and morbidity may correlate better with delay in recognition of the problem, duration of symptoms, onset of therapy, and type of complications, as opposed to the absolute degree of hypoglycemia or persistence of elevated insulin concentrations. A significant correlation exists between the amount of insulin injected and either the total amount of dextrose used for treatment or the duration of dextrose infusion.¹³⁹ In a retrospective study of insulin overdose, 7 of 17 cases (41%) developed recurrent hypoglycemia between 5 and 39 hours after overdose despite oral feeding and intravenous dextrose infusion ranging from 5 to 17 g of dextrose per hour.

In a retrospective review of 40 patients with sulfonylurea overdoses, the time from ingestion to the onset of hypoglycemia, when known, was variable.¹⁰⁵ The longest delay was 21 hours after ingestion of glyburide and 48 hours after ingestion of chlorpropamide. In a retrospective poison center review of 93 cases of sulfonylurea exposures in children, 25 patients (27%) developed hypoglycemia, with a time of onset ranging from 0.5 to 16 hours and a mean of 4.3 hours.¹¹⁸ In a prospective poison center study of sulfonylurea exposures in children, 56 of 185 (30%) patients developed hypoglycemia, with a time of onset ranging from 1 to 21 hours and a mean of 5.3 hours.¹³⁶ Single-tablet ingestions of chlorpropamide 250 mg, glipizide 5 mg, and glyburide 2.5 mg can result in hypoglycemia in young children,¹¹⁸ and the hypoglycemia may be delayed.¹⁴³ Hypoglycemia did not occur until 45 hours after ingestion of a 10 mg extended-release glipizide tablet in a 6 year-old child.¹⁰⁸

Hypoglycemia is reported in at least two cases of metformin overdose.¹⁴⁴ In both cases, metabolic acidosis with elevated lactate was evident on initial presentation. Hypoglycemia was present initially in one of the cases but did not develop until 7 hours later in the second case. Hypoglycemia and metabolic acidosis with hyperlactatemia are reported in a case of overdose with metformin, atenolol, and diclofenac.⁵² Hypoglycemia is reported in a case of metformin-associated metabolic acidosis with hyperlactatemia related to therapeutic use.⁶⁹ Insufficient evidence supports the concept that metformin-associated hypoglycemia can develop in a patient who is not critically ill without metabolic acidosis. Because many patients receiving metformin also take sulfonylureas, hypoglycemia should be anticipated after overdose. Phenformin is similar to metformin in that ingestion alone rarely causes hypoglycemia, in overdose or following therapeutic use.¹³⁰

The α -glucosidase inhibitors, thiazolidinediones, meglitinides, GLP-1 analogs, gliptins, and amylin analogs are xenobiotics for which overdose data are limited. Acarbose and miglitol are not likely to cause hypoglycemia based on their mechanism of action of inhibiting α -glucosidase. The most common adverse effects associated with therapeutic use of these xenobiotics are gastrointestinal, including nausea, bloating, abdominal pain, flatulence, and diarrhea. Elevated aminotransferase concentrations were noted after use of acarbose in clinical trials.⁵⁷ Most patients were asymptomatic, and the aminotransferase concentrations returned to normal after the drug was discontinued. The therapeutic use of acarbose in some cases reportedly led to hepatotoxicity that resolved after the drug was discontinued.^{5,24}

Hypoglycemia would not be expected after thiazolidinedione overdose. The most serious adverse effect of troglitazone is the development of liver toxicity with therapeutic doses, which in some cases was severe enough to require liver transplantation.^{49,99} Liver toxicity related to therapeutic use of rosiglitazone^{3,46} and pioglitazone is also reported.^{82,85} Therapeutic use of pioglitazone and rosiglitazone may precipitate fluid retention in patients with underlying congestive heart failure.⁹⁸ A meta-analysis concluded that rosiglitazone therapy is associated with an increased risk of myocardial infarction and death from cardiovascular causes.¹⁰¹

Hypoglycemia should be anticipated after repaglinide and nateglinide ingestion. Hypoglycemia is reported after nateglinide overdose,⁹⁶ and a case of intentionally self-induced hypoglycemia secondary to repaglinide is reported.⁵⁵ Hypoglycemia did not occur in a recently published case of intentional overdose with a total of 90 μ g exenatide.²⁹ “Severe hypoglycemia” was reported in a phase III clinical trial after inadvertent administration of 10 times the normal dose of exenatide. The specific glucose concentration is not noted in the report.²² Pramlintide is used therapeutically in conjunction with insulin, and hypoglycemia in this setting is more likely than with insulin use alone.⁷⁷

DIAGNOSTIC TESTING

Suspicion of hypoglycemia, particularly neuroglycopenia, is important in any patient with an abnormal neurologic examination. The most frequent reasons for failure to diagnose hypoglycemia and mismanaging patients are the erroneous conclusions that the patient is not hypoglycemic but rather is psychotic, epileptic, experiencing a CVA, or intoxicated because of an “odor of alcohol” on the breath (Chap. 80). Compounding the problem of misdiagnosis is the erroneous assumption that a single bolus of 0.5 to 1 g/kg of hypertonic dextrose will always be sufficient.

Plasma glucose concentrations are accurate, but treatment cannot be delayed pending the results of laboratory testing.

Glucose reagent strip testing can be performed at the bedside. The sensitivity of these tests for detecting hypoglycemia is excellent, but these tests are not perfect. Several interfering substances may cause false elevation of bedside glucose reagent strip concentrations, including maltodextrin, acetaminophen, bilirubin, triglyceride, and uric acid.^{39,65} Bedside glucose testing is discussed in more detail in Antidotes in Depth: A12.

Diagnostic studies other than determinations of glucose concentrations may be indicated, depending on the clinical situation. In some instances, determination of serum ethanol concentration may be helpful in confirming alcohol as a contributing or sole etiologic factor. Kidney function tests may indicate the presence of kidney impairment as a causative factor of hypoglycemia. This commonly occurs in diabetics taking insulin, who often develop kidney failure after they have had the disease for several years. Insulin half-life increases as kidney function declines. Measures of hepatic function may be a clue to liver disease as a cause of hypoglycemia, although liver disease may also be evident on physical examination. Seizures are commonly associated with hypoglycemia, but other studies, such as electrolytes, calcium, magnesium, and imaging of the brain, may be indicated if doubt about the etiology exists.

In the majority of overdose cases, laboratory testing for specific antidiabetics is not helpful. Exceptions might include malicious, surreptitious, or unintentional overdoses (discussed in the next section). Metformin concentrations vary and do not necessarily correlate with the clinical condition.^{2,71,72}

For known diabetics in whom overdose is not suspected, the clinician must search diligently for the cause of hypoglycemia. Sometimes it is as simple as a missed meal in an insulin user or an unusually strenuous exercise routine, but in many cases the cause cannot be clearly defined. Numerous medical conditions, as well as a variety of medications, may be involved (Table 53–1), and diagnostic testing must be individualized for each episode depending on the clinical suspicion. Diagnosing the etiology as “idiopathic” is never acceptable.

EVALUATION OF MALICIOUS, SURREPTITIOUS, OR UNINTENTIONAL INSULIN OVERDOSE

The physical examination may provide helpful clues to the evaluation of a suspected malicious, surreptitious, or unintentional insulin overdose. A meticulous search may reveal a site that is erythematous, hemorrhagic, atypically boggy in nature, or even painful if the subcutaneous (or intramuscular) injection of insulin was particularly large. A simple unexplained needle puncture mark in the appropriate clinical setting may suggest insulin injection.

An understanding of how the β cells of the pancreas secrete insulin in response to glucose concentrations in the blood is essential to understanding the investigation of fasting hypoglycemia.³¹ When the plasma glucose concentration is less than 45 mg/dL, insulin secretion should be almost completely suppressed, so plasma insulin concentrations should be minimal or absent.¹¹⁴ Moreover, insulin is secreted as proinsulin, which is cleaved in vivo to form insulin (a double stranded peptide) and C-peptide, which are released into the blood in equimolar quantities. Insulin is biologically active, whereas proinsulin has limited activity, and C-peptide has no activity. Although insulin is normally cleared during hepatic transit, C-peptide is not. For this reason, C-peptide can be utilized as a quantitative marker of endogenous insulin secretion. In contrast, commercially available exogenous human insulin does not contain C-peptide fragments (Table 53–5). When plasma glucose concentration falls to hypoglycemic concentrations (usually less than 60 mg/dL), insulin concentration should fall to less than 6 μ U/mL. If hypoglycemia is caused by exogenous insulin administration, plasma C-peptide concentrations should be less than 0.2 nmol/L in the presence of insulin concentrations that are substantially higher than insulin concentrations resulting from an insulinoma. With insulinoma, insulin concentrations generally are greater than 6 μ U/mL in the presence of hypoglycemia. Insulinoma results in elevations of both C-peptide and insulin concentrations. Sulfonylurea overdose is expected to have similar effects, but concentrations in reported cases of sulfonylurea-induced hypoglycemia vary considerably.³⁶ In the face of uncertainty, sulfonylurea concentrations are available from reference laboratories. Animal insulin can be distinguished from human insulin by high performance liquid chromatography.⁵⁰ However, this technique has limited use because of the virtually exclusive use of human insulin at present.

TABLE 53–5. Laboratory Assessment of Fasting Hypoglycemia

Clinical State	Insulin ^a (Serum) (μU/mL)	C-Peptide (Serum) (nmol/L)	Proinsulin Serum (pmol/L)	Antinsulin Antibodies ^d
Normal	<6	<0.2	<5	–
Exogenous insulin	Very high	Low (suppressed)	Absent	Present ^c
Insulinoma	High	High	Present	Absent
Sulfonylurea ingestion ^d	High	High	Present	Absent
Autoimmune	Very high (artifact)	Low (or) high (artifact)	Present	Present
Decreased glucose production	Low	Low	Present	Absent
Neoplasia (non-β-cell)	Low	Low	Present	Absent

^aInsulin concentrations are determined during fasting induced hypoglycemia at low concentrations, preferably <60 mg/dL of plasma glucose. ^bThe antinsulin antibodies produced spontaneously differ from those of treated (exposed to exogenous insulin) and those of untreated insulin dependent diabetics. ^cThe presence of antinsulin antibodies occurs less frequently in those exposed only to human insulin. ^dSulfonylurea ingestion is diagnosed by detection of the drugs or their metabolites in serum or urine.

In summary, patients with exogenous insulin induced hypoglycemia will have high insulin concentrations, the presence of insulin-binding antibodies (if chronic insulin users),⁴³ and low C-peptide concentrations. Those who have taken sulfonylureas will have high insulin concentrations, absent insulin-binding antibodies, high C-peptide concentrations, and presence of urinary sulfonylurea metabolites (Table 53–5). The issues of evidence collection that are appropriate to document malicious or surreptitious use of insulin successfully are described⁸⁰ (Chap. 141).

MANAGEMENT

Treatment centers on the correction of hypoglycemia and the anticipation that hypoglycemia may recur. Symptomatic patients with hypoglycemia require immediate treatment with 0.5 to 1 g/kg concentrated intravenous dextrose in the form of D₅₀W in adults, D₂₅W in children, and D₁₀W in neonates. Occasionally, patients require a larger dose to achieve an initial response. If hypoglycemia is suspected but not confirmed, as in the absence of rapid reagent strip availability or when such readings are “borderline,” dextrose should be administered. Theoretical risks are associated with use of concentrated dextrose in the setting of cerebral ischemia, but failure to rapidly correct hypoglycemia may lead to deleterious neurologic effects. Appropriate emergency and toxicologic uses of hypertonic dextrose are covered in detail in Antidotes in Depth: A12.

Glucagon should not be considered as an antihypoglycemic except in the uncommon situation where intravenous access cannot be obtained. Glucagon has a delay to onset of action and may be ineffective in patients with depleted glycogen stores, as in the elderly, cancer patients, or alcoholics. Glucagon also stimulates insulin release from the pancreas, which may lead to prolonged hypoglycemia in settings such as sulfonylurea ingestion and insulinoma.¹⁴⁵

Numerous studies have evaluated approaches for treating insulin reactions with carbohydrates in tablet, solution, or gel forms in a well-defined diabetic population.¹³³ None of these forms is appropriate for the undifferentiated, possibly hypoglycemic patient if intravenous access is available.

A common occurrence involves symptomatic hypoglycemic patients who receive intravenous dextrose in the prehospital setting and subsequently refuse transport to the hospital. The authors of a retrospective review of 571 paramedic runs involving hypoglycemic patients concluded that out-of-hospital treatment of hypoglycemic diabetic patients is safe and effective even when transport is refused.¹³⁴ However, of the 159 patients who agreed to hospital transport, 40% were admitted. The admitted group was older than those released from the ED. The admission rate for transported patients on oral hypoglycemics was higher than those on insulin. The reasons for admission are not otherwise detailed. The authors of a prospective study involving 132 hypoglycemic diabetic patients who refused transport after therapy concluded that most such patients have good short-term outcome, but they still encouraged transport because of the risk of recurrent hypoglycemia.⁹¹ One patient died in each of these two studies. A prospective study in 35 patients with 38 hypoglycemic events related to insulin use concluded that most patients were successfully treated in the prehospital setting without transport.⁷⁸ However, two patients developed recurrent hypoglycemia that they treated themselves, and one of these patients required placement in a long-term care facility for posthypoglycemic encephalopathy. We therefore recommend that all hypoglycemic patients should be transported to EDs.

Emesis, lavage, and catharsis are of limited benefit in the management of patients who overdose on hypoglycemics. The extensive affinity between chlorpropamide, tolazamide, tolbutamide, glyburide, glipizide, and activated charcoal is demonstrated in vitro.⁶² The affinities ranged from 0.45 to 0.52 g/g activated charcoal at pH 7.5 and were higher at pH 4.9. Single-dose activated charcoal should be beneficial in the management of these overdoses. Although affinity studies are

lacking for the other oral hypoglycemics, their chemical characteristics are such that single-dose activated charcoal is expected to be beneficial for these overdoses as well. Multiple-dose activated charcoal and whole-bowel irrigation may be of benefit and should be considered after overdose of modified-release antidiabetics and hypoglycemics, but outcome studies are not available.

In patients who overdose on insulin, case reports describe the use of surgical excision of the injection site.^{23,79,87} However, this technique has not been studied in a systematic fashion, until then, it is expected that IV dextrose should be sufficient. Needle aspiration of a depot site is less invasive and should be considered.

Urinary alkalinization to a pH of 7 to 8 can reduce the half-life of chlorpropamide from 49 hours to approximately 13 hours. Urinary alkalinization is not useful for other hypoglycemics because of their limited renal excretion.¹⁰⁰

MAINTAINING EUGLYCEMIA AFTER INITIAL CONTROL

After the patient is awake and alert, further therapy depends on the xenobiotic involved and pancreatic islet cell function. Some patients, particularly those with prolonged hypoglycemia, may have persistent altered mental status despite euglycemia. Whether the event was unintentional or intentional with suicidal or homicidal intent must be determined. One problem associated with dextrose administration occurs in individuals who can produce insulin via glucose-stimulated insulin release (nondiabetics and those with type 2 diabetes mellitus), placing them at substantial risk for recurrent hypoglycemia. This complication can occur with insulin overdose but is particularly problematic with overdoses of sulfonylurea or meglitinide because these hypoglycemics stimulate insulin release. Treatment with hypertonic dextrose solutions can be expected to result in dramatic yet only transient increases in glucose concentrations, with a subsequent fall in plasma glucose concentration, possibly back to hypoglycemic concentrations.

For diabetics who unintentionally inject an excessive amount of insulin and are not neuroglycopenic, feeding should be initiated and intravenous access maintained while avoiding routine dextrose infusion. In the event of recurrent symptomatic hypoglycemia, a concentrated dextrose bolus should be used. Overdose in the setting of suicidal or homicidal intent likely involves significant quantities of insulin. Nondiabetics may be particularly prone to significant hypoglycemia because they lack insulin resistance. Feeding should be initiated and glucose concentrations maintained in the 100 to 150 mg/dL range using a concentrated dextrose infusion (D₁₀W or greater) as needed.

Central venous lines should be used when D₂₀W infusion is instituted, because concentrated dextrose solutions are substantial venous irritants. The presence of glycosuria is not an adequate indicator of euglycemia; frequent serial blood or reagent strip glucose concentrations should be obtained. The appropriate timing of glucose monitoring varies depending on the clinical situation. Mental status must be observed. As a rough guide, glucose monitoring every 1 to 2 hours after initial control is reasonable, with subsequent spacing of the intervals to once every 4 to 6 hours. Phosphate concentrations should be monitored because glucose loading may lead to hypophosphatemia.⁹² Potassium concentrations should be monitored because glucose administration may lead to hypokalemia in nondiabetics and hyperkalemia in patients with impaired insulin secretion.²⁸ The duration of sampling depends on the stability of the patient, the underlying metabolic disorders, the extent of overdose, and the rate of improvement. When the patient begins to eat an adequate diet and the initial hypoglycemia is controlled, the plasma glucose concentration will rise, and the concentration and rate of dextrose infusion can be tapered. Many patients may actually develop significant hyperglycemia.

The therapeutic approach differs for patients who overdose on sulfonylureas or meglitinides. After initial control of hypoglycemia with concentrated dextrose, the patient should be fed. Intravenous access is necessary, but routine dextrose infusion should be avoided. As with insulin overdose, frequent monitoring of glucose concentrations and mental status is critical. We recommend early use of octreotide in this setting because of the significant risk of glucose stimulated insulin release.

Octreotide, a semisynthetic long-acting analog of somatostatin with an intravenous half-life of 72 minutes, inhibits glucose-stimulated β cell insulin release via receptors coupled to G proteins on β islet cells.¹³ Somatostatin is present in diverse tissues such as the hypothalamus, pancreas, and gastrointestinal tract. It alters the secretion of growth hormone and thyroid-stimulating hormone, gastrointestinal secretions, and the endocrine pancreas (glucagon and insulin).^{122,123} Octreotide was compared to intravenous hypertonic dextrose and to diazoxide and concomitant dextrose in normal subjects brought to hypoglycemia using glipizide.¹³ Fewer episodes of recurrent hypoglycemia occurred after octreotide therapy, and overall dextrose requirements were lower than in the dextrose-alone and dextrose-plus-diazoxide groups. Several successful clinical experiences with octreotide are reported with quinine-induced hypoglycemia resulting from malaria therapy,¹¹¹ insulinoma,⁵⁴ nesidioblastosis of infancy,³⁴ hypoglycemia related to therapeutic use of gliclazide,¹⁶ and tolbutamide overdose.¹³ In a retrospective study of nine patients with hypoglycemia resulting from either glyburide or glipizide, octreotide effectively reduced the risk of recurrent hypoglycemia.⁸⁸

Octreotide appears to be relatively free of serious side effects. The most likely adverse effects are injection-site discomfort if it is administered subcutaneously and gastrointestinal symptoms such as nausea, bloating, diarrhea, and constipation.⁸¹ The suggested adult octreotide dose is 50 μ g subcutaneously every 6 hours (Antidotes in Depth: A13). The

patient should be monitored for 12 to 24 hours after the last dose of octreotide. This observation will ensure that recurrence of hypoglycemia does not occur. Like octreotide, diazoxide may be effective in patients with refractory sulfonylurea-induced hypoglycemia.^{60,104} However, because of its potential to cause hypotension, diazoxide should be considered only if octreotide is unavailable.

ADMITTING PATIENTS TO THE HOSPITAL

The decision to admit a patient may be complex, but several guidelines can be followed. Admission is required for hypoglycemia related to sulfonylureas, ethanol, starvation, hepatic failure, and kidney failure and for hypoglycemia of unknown etiology. The decision to admit a patient often depends on finding an etiology for hypoglycemia, particularly in the setting of insulin use. In most cases, if a diabetic patient on therapeutic doses of insulin develops hypoglycemia after a missed meal, the patient can be discharged after a 4 to 6 hour observation period during which the individual eats a meal and remains asymptomatic with no evidence of hypoglycemia. Patients receiving therapeutic doses of insulin require inpatient evaluation of recurrent and unexplained hypoglycemic episodes. All patients with hypoglycemia after unintentional overdose with long-acting insulin should be admitted. Hospitalization is recommended after unintentional overdose with ultrashort-acting, short-acting, or intermediate-acting insulin if hypoglycemia is persistent or recurrent during a 4 to 6 hour observation period in the ED. Many factors may be responsible for unintentional insulin overdose, such as patient error because of impaired vision, syringe structure, and prescription error; hospital admission may be warranted. Admission is indicated for any patient, regardless of serum glucose concentration or presence or absence of symptoms, who intentionally overdoses on a sulfonylurea or any form of injected insulin, because delayed, profound, and protracted hypoglycemia may result. Although intravenous insulin overdose is expected to result in more immediate symptoms, experience with this scenario is limited. Admission in this setting is advised unless short-acting insulin is involved. Glargine is expected to act like regular insulin when administered intravenously. It is long-acting when administered subcutaneously due to the formation of microprecipitates which are absorbed slowly. Hypoglycemia related to sulfonylurea use in any setting requires hospitalization.²⁰

Patients with possible intentionally self-induced hypoglycemia should be admitted. Intentionally self-induced hypoglycemia is most commonly recognized by members of the medical profession. Administration of insulin to a nondiabetic child is a form of child abuse or an attempt at homicide³⁷ (Chap. 32). Children who have been given an inappropriate dose of insulin, as well as any patient who may be a victim of attempted homicide, should be admitted.

A 4 to 6 hour observation period is recommended after metformin overdose. Further observation or hospital admission is not required for patients who remain asymptomatic during this period with no evidence of metabolic acidosis or hypoglycemia. Patients who overdose on α -glucosidase inhibitors are not expected to have delayed or serious systemic toxicity, and routine medical admission is unnecessary. There are limited data regarding the risk of hypoglycemia and other adverse events after thiazolidinedione ingestion. Based on the mechanism of action and existing clinical experience, hypoglycemia is possible but uncommon after thiazolidinedione overdose. Delayed onset of hypoglycemia or other serious clinical manifestations is unlikely. A 4 to 6 hour observation period after thiazolidinedione overdose is recommended. Significant hypoglycemia is reported with nateglinide overdose,⁹⁶ and with repaglinide used in a setting of intentionally self-induced hypoglycemia.⁵⁵ Meglitinides are expected to behave pharmacologically like sulfonylureas. For this reason alone, hospital admission after meglitinide overdose is advisable, even when the patient is asymptomatic. Admission after exenatide, liraglutide, sitagliptin, saxagliptin, linagliptin, and pramlintide overdose is advised until more overdose data are obtained. Delays in onset of clinical manifestations, particularly hypoglycemia, are not expected, but there is currently limited clinical experience with regard to overdose.

Children who unintentionally ingest one or more sulfonylurea tablets should be hospitalized for 24 hours. Although this recommendation may be controversial and some authors suggest shorter observation periods²¹ or even home monitoring in some cases,¹²⁴ we believe that delayed hypoglycemic effects of sulfonylurea ingestion in children are well documented^{118,136,143} and convincing enough to support admission in all cases. Asymptomatic children with single tablet exposures to sulfonylureas are best managed without prophylactic intravenous dextrose, which could contribute to delayed onset of hypoglycemia.²¹ Elevations in glucose concentrations stimulate insulin release by the pancreas. Such patients instead are best managed by early feeding, frequent checks of glucose concentrations, and observation of mental status.

METFORMIN-ASSOCIATED METABOLIC ACIDOSIS WITH HYPERLACTATEMIA

Throughout this chapter, the term metabolic acidosis with hyperlactatemia is used rather than metformin-associated lactic acidosis. The biochemical and pathophysiologic processes involving lactate are complex, but a few points are worth summarizing. Hyperlactatemia occurs in various diseases and can be present in the absence of acidosis. The production of lactic acid does not result in a net increase in hydrogen ion concentration unless there is associated impairment of oxidative

metabolism. Impaired oxidative metabolism leads to an increase in hydrogen ion production through the hydrolysis of ATP.⁹³ In a pig overdose model, metformin caused metabolic acidosis with hyperlactatemia, mitochondrial dysfunction, and inhibition of oxygen consumption. Infusion of lactic acid alone did not cause inhibition of oxygen consumption.¹¹⁷

The biguanides are uniquely associated with the occurrence of metabolic acidosis with hyperlactatemia. Phenformin causes lactic acid production by several mechanisms, including interference with cellular aerobic metabolism and subsequent enhanced anaerobic metabolism. Phenformin suppresses hepatic gluconeogenesis from pyruvate and causes a decrease in hepatocellular pH, resulting in decreased lactate consumption and hepatic lactate uptake. Metformin-associated metabolic acidosis with elevated lactate occurs 20 times less commonly than that occurring with phenformin. In isolated perfused rat liver, metformin inhibits both hepatic lactate uptake and conversion of lactate to glucose.¹¹⁹ Metabolic acidosis with hyperlactatemia related to metformin usually occurs in the presence of an underlying condition, particularly kidney impairment.^{25,69} In this setting, increased tissue burden of metformin, which is renally eliminated, probably occurs. Other risk factors include cardiorespiratory insufficiency, septicemia, liver disease, history of metabolic acidosis with hyperlactatemia, advanced age, alcohol abuse, and use of radiologic contrast media.^{9,25} Iodinated contrast material may induce acute kidney injury, leading to accumulation of metformin and subsequent risk of development of metabolic acidosis with hyperlactatemia. However, the risk of developing metabolic acidosis with hyperlactatemia after contrast administration is low in patients taking metformin who have normal kidney function and no other risk factors.^{86,97}

Severe metabolic acidosis with hyperlactatemia occurs after acute metformin overdose^{72,89,104,144} but appears to be uncommon. In one case,⁸⁹ metabolic acidosis was not diagnosed until 14 hours after metformin overdose. The patient had early symptoms of repeated vomiting at 1 hour postingestion. Metabolic acidosis with hyperlactatemia occurred in two of 65 adult metformin overdose cases reported to a poison center¹³⁷ and was not reported in a poison center series of 55 pediatric metformin exposures.¹³⁸ In a retrospective review of 398 cases of acute metformin overdose from two poison centers, metabolic acidosis with hyperlactatemia occurred in 9.1% of single product overdose and in 0.7% of polypharmacy overdoses.¹⁵²

A systematic review from the Cochrane Library concluded that therapeutic use of metformin is not associated with an increased risk of metabolic acidosis with hyperlactatemia compared with other antidiabetic treatments if no contraindications are present.¹²⁵ This conclusion was based on a review of prospective comparative trials and observational cohort studies. However, the risk of metformin-associated metabolic acidosis with hyperlactatemia in the setting of overdose setting or kidney insufficiency was not assessed. Although metabolic acidosis with hyperlactatemia after overdose is not common, it does occur with sufficient frequency to require vigilance on the part of the treating physician. Case reports were not used in the Cochrane review, and a few cases of metformin-associated metabolic acidosis with hyperlactatemia in the setting of therapeutic use with no underlying risk factors are reported.^{25,109,147}

It is difficult to predict outcome after metformin overdose. A retrospective literature review found no deaths in cases with a nadir serum pH greater than 6.9, a peak serum lactate concentration less than 25 mmol/L, or a peak serum metformin concentration less than 50 µg/mL.³⁵ However, a retrospective review of intensive care unit patients with metabolic acidosis with hyperlactatemia found no association between metformin concentrations in survivors and nonsurvivors.¹²⁹ There was an association between mortality and lactate concentrations and pH.

Metformin associated metabolic acidosis with hyperlactatemia is a potentially lethal condition. Recognition and awareness of this disorder are important. Symptoms may be nonspecific and include abdominal pain, nausea, vomiting, malaise, myalgia, and dizziness. However, gastrointestinal symptoms are common adverse effects associated with therapeutic use of metformin and do not necessarily require discontinuation of the drug. More severe clinical manifestations of metformin-associated metabolic acidosis with hyperlactatemia include confusion, blindness, mental status depression, hypothermia, respiratory insufficiency, and hypotension. Serum metformin concentrations can be obtained as a diagnostic aid, but these may not correlate with the clinical condition in both the acute overdose setting and in the setting of therapeutic metformin use.^{71,72}

Aggressive airway management and vasopressor therapy may be required. Indications for use of intravenous sodium bicarbonate in critically ill patients with metabolic acidosis with hyperlactatemia of various etiologies are poorly defined and controversial. Rather than using an arterial pH cutoff, we recommend using sodium bicarbonate given evidence of impaired buffering capacity based on a serum bicarbonate threshold concentration of less than 5 mEq/L. Based on case reports, hemodialysis may be effective in improving acid–base status and clinical outcome in patients with significant metabolic acidosis with hyperlactatemia.^{53,69,73} In some of these cases, metformin concentrations were measured and remained abnormally high after dialysis. Clinical improvement despite inadequate removal of metformin may be related to correction of acid–base status.

SUMMARY

- Numerous xenobiotics and medical conditions may cause hypoglycemia.

- Hypoglycemia is the predominant adverse effect related to therapeutic use and overdose of many of the drugs used for treatment of diabetes mellitus.
- Various clinical manifestations, particularly neurologic, may occur and can be confused with conditions such as ethanol intoxication, psychosis, epilepsy, and cerebrovascular accidents.
- The potential for delayed and prolonged hypoglycemia must be recognized in overdose situations.
- Although several treatment options exist, rapid intravenous administration of dextrose is the most important measure.
- Octreotide is useful for patients with recurrent hypoglycemia following sulfonylurea or meglitinide overdose.

A12 ANTIDOTES IN DEPTH

Dextrose (D-Glucose)

Larissa I. Velez and Kathleen A. Delaney

Dextrose (D-glucose)

INTRODUCTION

Hypoglycemia is a common cause of altered mental status. Although classically associated with tachycardia, tremor, and diaphoresis, the predictive value of these manifestations is too low to be relied upon. As a result, all patients with altered consciousness require either rapid point-of-care testing of their glucose concentrations or empiric treatment for presumed hypoglycemia. When rapidly diagnosed and treated, hypoglycemic patients typically recover without sequelae. However, delayed or incomplete therapy may lead to permanent neurologic dysfunction ([Chap. 53](#)).

HISTORY

In 1891, Fisher performed the unbelievable feat of identifying the 16 possible different spatial configurations of aldohexose ($C_6H_{12}O_6$), the most prominent member being dextrose or D-glucose.³⁸ This discovery won him the 1902 Nobel Prize in chemistry. The diverse manifestations of hypoglycemia and the treatment of severe cases with intravenous (IV) dextrose have been appreciated for decades.⁶⁸

PHARMACOLOGY

Chemistry

Sugar is the general term used for sweet carbohydrates that are used as food. Simple sugars are called monosaccharides and include glucose (also known as dextrose, or D-glucose, as the L-isomer is hardly found in nature), fructose (also known as fruit sugar, the sweetest), and galactose. The disaccharides include maltose, lactose, and sucrose (sucrose is also known as table or granulated sugar).

Sugars are found in the tissues of most plants, but are only present in sufficient concentrations for efficient extraction in sugarcane and sugar beet. Commercially, glucose is produced from the hydrolysis of starch. Several crops serve as the starch source, with maize being the most common in the United States.

In humans, carbohydrates are absorbed and transported via two main systems. Sodium-dependent glucose transporters (SGLT1-6) are responsible for the intestinal glucose absorption.¹³ Their discovery represented the first description of the mechanism of “flux coupling” or cotransporting, in which transporting one substrate down its concentration gradient creates energy that can then be used to transport a second substrate against a concentration gradient. Other facilitative sugar transporters include GLUT1 to GLUT14 and HMIT.¹⁰⁷ GLUT4 is expressed in insulin-sensitive tissues and regulates whole-body glucose homeostasis.⁷⁸ GLUT3 is found in neurons and in the placenta and has a high affinity for glucose, allowing for transport even in low substrate conditions.⁷ GLUT5 is responsible for the absorption of fructose in the small intestine.⁹ The GLUT5 transporter has wide variability and is dependent on the amount of glucose ingested relative to the fructose. Decreased fructose absorption can lead to abdominal bloating and osmotic diarrhea in susceptible individuals.⁵⁵

Binding of glucose to one of the GLUT receptors causes a conformational change that results in glucose translocation across the membrane.⁵⁴

Related Xenobiotics

Besides the mono and disaccharides mentioned above, sugars are also found in polymer forms. Maltodextrins are oligosaccharides of D-glucose used as food additives. Starch and cellulose are the polymers of glucose found in plants. Glycogen and chitin are found in animals. Some of the polymers are used to store energy (starch and glycogen) and some are used for structural support (chitin and cellulose).

Mechanism of Action

Glucose reaching the liver, adipose tissue, and muscle cells is absorbed and stored as glycogen (under the influence of insulin) or used by all cells to produce adenosine triphosphate (ATP) and pyruvate via glycolysis. Hepatic glycogen can later be converted to glucose and returned to the blood when insulin is low or absent. In contrast, glycogen found in muscle and adipose cells is utilized internally and not released into the systemic circulation. Some glucose is converted to lactic acid by astrocytes and then utilized as an energy source. The brain can use both exogenous and endogenous lactate as an alternative energy source.^{94,105,112} Finally, glucose is also directly used by intestinal cells and red blood cells.

Pharmacokinetics

Accurate prediction of the amount of dextrose required to effectively treat patients with hypoglycemia is difficult. At equilibrium, 25 g of dextrose distributed in total body water in a 70 kg adult is calculated to increase the serum glucose concentration by about 60 mg/dL.⁵¹ In the few clinical studies performed, the magnitude of glucose elevation after oral or IV dextrose loading was unpredictable. In one study, 25 g (50 mL) of D₅₀W administered to adults (both diabetics and nondiabetics) resulted in a mean blood glucose elevation of 166 mg/dL when measured in the opposite extremity 3 to 5 minutes after the bolus; however, the range of this elevation was 37 to 370 mg/dL above baseline.¹ In a human model of insulin-induced hypoglycemia, oral administration of 10 or 20 g of dextrose increased the serum glucose concentration from 60 to 120 mg/dL over one hour.¹¹⁹ Another study used 25 volunteers and administered 25 g of IV dextrose as D₅₀W. Glucose concentrations were measured at 5, 15, 30, and 60 minutes. Volume of distribution formulas could not accurately predict postinfusion glucose concentrations. The serum glucose elevation was statistically significant from baseline at 5 and 15 minutes, and glucose concentrations returned to baseline at 30 minutes postinfusion.⁵

Pharmacodynamics

ATP provides the metabolic energy that fuels all critical cellular processes in all organs. In the adult brain, the anaerobic and aerobic metabolism of glucose through glycolysis and the citric acid cycle, respectively, are the primary sources of ATP (Chap. 13). Although the adult brain can use fatty acids, amino acids, lactate, and ketones as alternate substrates for ATP synthesis, these are not adequate to sustain normal cerebral function in the setting of glucose deprivation. In contrast, in fetal and neonatal brains, glucose is the only substrate for ATP production.^{88,113}

Hypoglycemia cannot be defined by strict numerical values. Rather, it is best defined by organ dysfunction in the setting of inadequate glucose concentrations. The onset of hypoglycemia in both adults and children is followed rapidly by global cerebral dysfunction. In individuals with diabetes, the density and sensitivity of neuronal insulin receptors vary as a function of glycemic control, so that diabetic patients with poor glycemic control have fewer and less sensitive neuronal insulin receptors and may experience hypoglycemic symptoms at much higher concentrations of glucose than those who are normally euglycemic. An important study of diabetic patients demonstrated that the mean blood glucose concentration for symptomatic hypoglycemia in poorly controlled patients was 78 ± 5 mg/dL compared with $53 \pm$ mg/dL in well-controlled patients.⁸ This differential response to hypoglycemia is also described at higher glucose concentrations in poorly controlled versus intensely controlled diabetic patients.⁵⁷ Thus, neuroglycopenia may occur despite “normal” peripheral blood glucose concentrations.¹¹⁵ In rare cases, glucose-consuming cancer cells can produce large amounts of lactate (Warburg effect), which can be used by the brain as an alternate source of energy. Even in the presence of profound hypoglycemia, such patients remain asymptomatic.³²

Hypoglycemia may cause a myriad of neuropsychiatric sequelae that are clinically indistinguishable from those of other toxic-metabolic and structural brain injuries.^{19,27,72,76,97,114,121} In a case series, preexisting signs and symptoms included dizziness and tremulousness (8%); focal stroke syndromes (2%), movement disorders or seizures (7%), irritability, confusion, or bizarre behavior (30%), delirium, stupor, or coma (52%); and irreversible encephalopathy.⁷² These numbers are similar to those in a case series of patients with insulinomas.¹⁸ In cases of undifferentiated coma, both the absence of pupillary light reflex (sensitivity 83% and specificity 77%, positive predictive value {PPV} 70 and negative predictive value {NPV} 87, likelihood ratio {LR} 3.56) and the presence of anisocoria (sensitivity 39% and specificity 96%, PPV 86

and NPV 70, LR 9) are helpful in distinguishing structural from metabolic causes.¹¹⁰ Hypoglycemic hemiplegia is a well-recognized, although rare entity, and therein lies the relevance of a serum glucose measurement in patients with focal neurologic symptoms.⁷²

The heart is partially dependent on glucose as an energy substrate. Hypoglycemia causes myocardial stress that may manifest as angina and or dysrhythmias. There are two mechanisms postulated for hypoglycemia induced dysrhythmias. First, it causes K⁺ current inhibition, which results in QT prolongation.⁸⁰ This is aggravated by the systemic catecholamine response to hypoglycemia, which results in increased intracellular calcium, another dysrhythmogenic stimulus.^{29,67,75,79–81} Nocturnal hypoglycemia is associated with the “dead in bed” syndrome. The postulated mechanisms are hypotonia of the respiratory muscles with an impaired awakening, mediated by orexin-A neurons, and QT prolongation and other dysrhythmogenic effects of hypoglycemia.^{42,82} Counterregulatory hormone responses to hypoglycemia are also impaired by sleep.^{26,58}

ROLE IN HYPOGLYCEMIA

Table A12–1 summarizes some causes of hypoglycemia.

TABLE A12–1. Xenobiotics and Medical Conditions Associated with Hypoglycemia	
Xenobiotic	Medical Condition
Ackee fruit (<i>Blighia sapida</i>)	Hyperinsulinism
Jamaican vomiting sickness	Inborn errors of carbohydrate metabolism (eg, glycogen storage disease)
β-Adrenergic antagonists	Kidney disease
Angiotensin-converting enzyme inhibitors (rare)	Liver disease
Bitter melon (<i>Momordica charantia</i>)	Malignancy
Disopyramide	Malnutrition
Ethanol	Sepsis
Haloperidol (rare)	Shock
Insulin	Starvation
Insulinlike growth factor	Transient neonatal hypoglycemia
Pentamidine	
Quinine and quinidine	
Quinolones (especially gatifloxacin)	
Ritodrine	
Salicylate	
Streptozocin	
Sulfonylureas and other classes	
Trimethoprim-sulfamethoxazole	

Empiric Treatment Considerations

The history and physical examination do not reliably detect patients who are hypoglycemic.⁵⁰ Tachycardia, diaphoresis, pallor, hypertension, tremors, hunger, and restlessness tend to predominate when the decline in serum glucose concentration is rapid. However, neuroglycopenia, even when severe, may not trigger autonomic responses.¹⁹ Signs and symptoms may be further blunted or absent in the setting of concurrent use of β-adrenergic antagonists. Central nervous system signs of neuroglycopenia are also nonspecific. They may include visual disturbances, psychiatric disturbances, confusion, stupor, coma, seizures, and focal neurologic findings.^{72,98} In children, the only sign of neuroglycopenia may be lethargy or irritability.¹²³

The bedside diagnosis of hypoglycemia is limited by the sensitivity and specificity of reagent strips, which do not have the reliability and accuracy of laboratory analysis.⁸⁴ Sensitivities of commonly available reagent strips for detection of hypoglycemia range between 92% and 97% in various studies.^{11,12,56,66,71,96} The accuracy of these point-of-care testing methods is affected by the source of blood, whether arterial, venous, or capillary, and by the poor perfusion associated with shock and cardiac arrest.^{4,14,28,41,59,62,64,70,106}

False-positive capillary hypoglycemia occurs in shock and cardiac arrest. Hypoglycemia was identified by capillary samples in 8 of 50 patients with cardiac arrest. Only three of these were confirmed to be hypoglycemic by laboratory

determination of serum glucose. Reagent strip testing of venous blood correctly classified these patients. There were no false negative results.¹⁰⁶ A critical care unit study that evaluated patients in shock showed that 32% were incorrectly diagnosed as hypoglycemic when capillary blood was used. All these patients were either normoglycemic or hyperglycemic. Results of reagent strip tests of venous blood correlated well with laboratory results, correctly classifying all patients. No cases of hypoglycemia were missed.⁴ Therefore, capillary determinations of glucose should be used with caution in the critically ill population, recognizing that false positive detections of hypoglycemia are common.⁷⁰ When feasible, laboratory measurements should be obtained in these populations. A second best alternative is reagent strip testing of venous blood rather than capillary samples. However, it is important to know the specific test being used at a particular institution, as more recent reports have shown improved correlation between point-of-care testing and laboratory glucose measurements.^{60,64,117}

Several studies have compared the accuracy of standard reagent strips for the detection of hypoglycemia from capillary and venous blood compared with the gold standard of the laboratory. Two studies, one with 97 subjects⁴¹ and one with 270 subjects,⁶² evaluated the agreement between reagent strip determinations of capillary and venous blood glucose in healthy normoglycemic volunteers. In the larger study, 18% of subjects had a more than 15 mg/dL difference between capillary and venous reagent strip tests. In this study, capillary measurements were better correlated with the laboratory values. Whether these results have any clinical significance is not clear because none of the subjects were outside of the euglycemic range. However, the results suggest that the capillary blood glucose test has greater accuracy in the euglycemic range and in healthy individuals.

The “safe” number at which no cases of symptomatic hypoglycemia are missed by reagent strip testing is a subject of debate, because of the inherent risk of error from lack of sensitivity. In one study in which hypoglycemia was defined as a blood glucose concentration below 60 mg/dL, 2 of 33 hypoglycemic patients were not detected at the bedside. A cutoff of 90 mg/dL would have detected 100% of numerically hypoglycemic patients.⁶⁶ Based on these studies, it can be argued that a bedside reagent measurement of 90 mg/dL is a conservative cutoff for assurance of clinical euglycemia in all patients.

With reagent strip testing, variations in hematocrit and the presence of isopropyl alcohol in the sample may alter the accuracy of the test.^{6,46} In some specific tests, such as the one using glucose dehydrogenase pyrroloquinolinequinone (GDH-PQQ), accuracy may be affected by a number of interfering xenobiotics, such as serum acetaminophen concentrations greater than 80 mg/dL, a serum bilirubin concentration greater than 20 mg/dL, a serum galactose concentration greater than 10 mg/dL, a maltose concentration greater than 16 mg/dL, a serum uric acid greater than 10 to 16 mg/dL, serum triglycerides greater than 5000 mg/dL, and the presence of D-xylose in the sample. All of these result in falsely elevated glucose measurements.³¹ There are reports of interference with the use of IV fat emulsion therapy as an antidote.⁴⁷ Notably, icodextrin, an ingredient in peritoneal dialysis fluids, may result in overestimation of glucose measurements because it is metabolized to maltose. In several case reports and at least 18 cases reported in a review, this overestimation resulted in excess insulin administration and subsequent hypoglycemia.^{31,39,61,90} Glucose monitoring systems that use the GDH-PQQ method should not be used in patients using icodextrin in the peritoneal dialysis fluid.¹¹¹ Maltose is also contained in some immunoglobulin solutions, and the same interference can be expected.^{34,104} Glucose measurements by the GDH-PQQ and the amperometric methods are also affected by the hematocrit.^{103,117} Whereas hematocrits lower than 20% may result in falsely elevated glucose measurements, hematocrits higher than 55% may result in falsely low measured glucose concentrations.³¹ In a retrospective review of patients admitted to a hospital over a 12-month period, 1.2% were identified as having interfering substances. Of these, 36% had active orders for insulin. In this review, the most common interferences identified were a low hematocrit (44% of patients) and a high serum uric acid (29% of patients).³¹

One final consideration is in patients with salicylate toxicity ([Chap. 39](#)), in which serum glucose is not an accurate reflection of tissue glucose concentrations.¹⁰⁸ Salicylate poisoning is a relatively uncommon cause for drug-induced hypoglycemia.¹⁰² Salicylates uncouple oxidative phosphorylation, which results in increased intracellular glucose demands. Patients may demonstrate symptoms of neuroglycopenia despite normal serum glucose concentrations. Dextrose administration reverses the signs and symptoms,⁶³ and can improve survival.¹⁰⁸

Advances in monitoring technology include continuous glucose monitoring, which uses a sensor placed under the skin that measures interstitial fluid glucose.⁸⁹ These sensors are generally accurate at normal glucose concentrations. However, in situations where the serum glucose is fluctuating, changes in the interstitial glucose concentration may lag for up to 15 minutes. Patients are encouraged to measure the capillary blood glucose before making treatment decisions.¹²⁰ A noninvasive device that also measures interstitial glucose concentrations has been approved by the US Food and Drug Administration.²⁵

Patients with asymptomatic or minimally symptomatic hypoglycemia should be treated with oral carbohydrates (juice, milk, candy, or glucose tablets). For adults, the recommended dose of 20 g should result in symptom improvement in 15 to 20 minutes.¹⁵ Since this improvement may be transient, it is recommended that the initial glucose intake should be followed by a more substantial meal. For the patient unable (coma, seizures) or unwilling (from neuroglycopenia) to receive oral glucose, the IV route must be used. In an adult a bolus dose of 0.5 to 1.0 g/kg of IV dextrose is recommended. The

subsequent improvement in glucose concentration is transient and the patient should be monitored closely for recurrence.¹⁵ Generally, a dextrose infusion should follow the initial dextrose bolus,¹⁵ with the recognition that this supplies very little caloric content.

Rapid increases in serum glucose are sufficient to stimulate insulin release from the pancreas and may result in reactive (or rebound) hypoglycemia. Therefore, glucose concentrations must be closely followed after a bolus of concentrated glucose solutions. This effect is exaggerated in the patients who have ingested sulfonylureas.^{44,48}

ROLE IN ETHANOL DISORDERS

Alcoholic ketoacidosis (AKA) is a metabolic emergency. It occurs when drinkers cease or significantly decrease their food intake and have some degree of vomiting. The result is salt and water depletion with an anion gap metabolic acidosis that is typically accompanied by a normal to low serum glucose (unlike diabetic ketoacidosis). In children, hypoglycemia may occasionally ensue after exposure to ethanol and ethanol-containing household products.^{35,87} Newborns and young infants, in contrast to adults, may present with irritability, feeding problems, lethargy, cyanosis, tachypnea, and/or hypothermia.⁴⁹

The management of AKA consists of rehydration using isotonic crystalloids, parenteral thiamine administration, dextrose infusion using D₅W or D₁₀W, potassium replacement, and addressing the underlying medical problem that led to AKA.⁴⁰

Chapter 80 has an in-depth discussion of AKA.

ROLE IN SALICYLATE POISONING

As discussed in the previous section, salicylates uncouple oxidative phosphorylation, which results in increased intracellular glucose demands.¹⁰⁹ Patients with salicylate toxicity may demonstrate symptoms of neuroglycopenia despite normal serum glucose concentrations. Dextrose administration has been shown to reverse these signs and symptoms of neuroglycopenia.⁶³

Chapter 39 provides an in-depth discussion of salicylate toxicity and its management.

ROLE IN CARDIOVASCULAR TOXICITY

Hyperinsulinemia/euglycemia is one of the cornerstones of management of patients with drug induced cardiovascular toxicity. Insulin improves carbohydrate utilization by the cells and restores calcium fluxes. This improves cardiac contractility and allows for improved vascular tone.⁷⁴ The available data strongly support this approach in patients with calcium channel blocker toxicity, and there are also reports that describe benefit in cases of β -adrenergic antagonist toxicity.^{69,124} The initial bolus of 1 unit/kg and subsequent 1 unit/kg/h of regular insulin must be supplemented with sufficient dextrose to maintain euglycemia. The use of continuous dextrose infusions with insulin (insulin–euglycemia) as antidotal therapy for cardiovascular toxicity is reviewed in Antidotes in Depth: A17.

ROLE IN HYPERKALEMIA

Hyperkalemia occurs commonly in the emergency department, most often as a result of end stage kidney disease. It can represent an adverse medication reaction. IV insulin is used to redistribute potassium inside the cell. A dose of 10 units of regular insulin is usually followed by 25 g of IV 50% dextrose.¹¹⁸ The initial dextrose dose should be followed by a dextrose infusion, as a single bolus is not sufficient to prevent hypoglycemia at one hour.² The onset of action is less than 15 minutes and peaks at 30 to 60 minutes.¹¹⁸ This regimen results in an average serum potassium decrease of about 0.6 mEq/L.¹¹⁸

ADVERSE EFFECTS AND SAFETY ISSUES

The most serious complications associated with hypoglycemia are directly attributable to the failure to recognize and treat it. Most complications due to the administration of concentrated IV dextrose are either clinically insignificant or exceedingly rare. Phlebitis and sclerosis of veins may occur. Tissue necrosis may occur after soft tissue extravasation of D₅₀W and after inadvertent intraarterial injection.^{3,24} Inappropriately large boluses of D₅₀W in children are associated with seizures, brain hemorrhage, and hyperosmolar coma.⁹⁹ Anaphylactoid reactions are also rarely reported after the administration of D₅₀W.¹⁶

While prolonged glucose infusions without thiamine supplementation are associated with Wernicke encephalopathy in

at-risk patients, this does not occur if thiamine is administered proximate to the time of dextrose administration. Correction of hypoglycemia should not be delayed in order to administer thiamine (Antidotes in Depth: A24).⁹²

Dilute dextrose solutions should not be administered with blood as they can cause pseudoagglutination of erythrocytes. These solutions can also result in electrolyte dilution and excess intravascular volume. Most dextrose products are derived from corn, so they should not be used in patients with of severe corn allergy.

One final important consideration is the development of rebound hypoglycemia when dextrose is used to treat sulfonylurea-induced hypoglycemia (Chap. 53). In these cases, serial measurements of glucose and close patient monitoring should follow any dextrose boluses.⁷³

Concerns Regarding Elevated Blood Glucose Concentrations in Patients with Cerebral Ischemia

Studies of ischemic brain injury in a variety of animal models consistently demonstrate that higher blood glucose concentrations are associated with more extensive cerebral injury and worse outcomes.^{17,20–22,43,52,65,86,100,101} The clinical literature also demonstrates that the presence of hyperglycemia upon admission is associated with poorer outcomes in patients with acute ischemic stroke.^{23,33,53,83,85,116,122,125}

While concerns previously existed regarding provision of dextrose in the clinical scenario of potential cerebral ischemia, rapid bedside testing has essentially eliminated this consideration. Although underpowered, the Glucose Insulin in Stroke Trial—United Kingdom (GIST-UK) failed to show any mortality benefit from treatment of hyperglycemia in acute stroke patients.^{45,95} Additionally, it is now clear that attempts at intensive glucose control are associated with higher rates of hypoglycemia, which is related to increased mortality.^{36,37,91,93}

PREGNANCY AND LACTATION

Dextrose is a pregnancy category C (IV) and A (oral); studies have not been conducted regarding its safety to the fetus. Hypoglycemia is a serious concern for fetal well being, and the best evidence suggests that hypoglycemia in a pregnant woman should be approached in the same manner as in any nonpregnant patient. Although there are no data regarding the use of hypertonic dextrose in lactation, it is unlikely to be a concern, because even if the concentration of glucose in subsequent breast milk is a significantly increased, the effect will be transient.

DOSING AND ADMINISTRATION

In most cases, the rapid correction of hypoglycemia by the administration of 0.5 to 1 g/kg of concentrated IV dextrose (Table A12–2) immediately reverses neurologic and cardiac effects. However, prolonged or severe hypoglycemia may result in permanent brain injury, myocardial infarction, and death.^{10,30,77} Glucose should be monitored after concentrated dextrose administration. This is usually done within an hour after administration or if there is a change in the patient’s condition.

TABLE A12–2. Dosing of Dextrose

Age	Concentration	Bolus	Dose in mL/kg
Adult	D ₅₀ W (50% = 0.5 g/mL)	0.5–1.0 g/kg	1–2
Child	D ₂₅ W (25% = 0.25 g/mL)	0.5–1.0 g/kg	2–4
Infant	D ₁₀ W (10% = 0.1 g/mL)	0.5–1.0 g/kg	5–10

FORMULATION AND ACQUISITION

Dextrose is available as a 5%, 10%, 20%, or 50% solution for IV use. Concentrations greater than 10% should be infused via a central venous catheter, except in emergencies. Table A12–3 summarizes the most commonly available intravenous and oral preparations.

TABLE A12–3. Dextrose Preparations for Clinical Use

<i>Preparation</i>	<i>Volume (mL)</i>	<i>Concentration or Amount</i>
Dextrose 2.5% for injection, USP	1000	0.025 g/mL
Dextrose 5% for injection, USP	25, 50, 100, 150, 250, 500, 1000	0.05 g/mL
Dextrose 10% for injection, USP	5, 250, 500, 1000	0.10 g/mL
Dextrose 20% for injection, USP	500, 1000	0.20 g/mL
Dextrose 25% for injection, USP	10	0.25 g/mL
Dextrose 50% for injection, USP	50	0.50 g/mL
Dextrose 70% for injection, USP	70	0.70 g/mL
Oral		
Glucose tablets		1 or 4 g/tablet
Glucose gel		0.4 g/mL (40%)
Dextrose liquid		15 g/59 mL
Dextrose 5% oral solution		0.05 g/mL

USP = US Pharmacopeial Convention.

SUMMARY

- Dextrose is an effective antidote for patients with hypoglycemia and has additional indications in those with alcoholic ketoacidosis and as an adjunct to high-dose insulin therapy for cardiovascular drug toxicity.
- Hypoglycemia can mimic many syndromes, producing any alteration in consciousness, including focal neurologic syndromes.
- The currently available reagent strips reliably demonstrate the absence of significant hypoglycemia at readings greater than 90 mg/dL. Profound neurologic impairment likely is not the result of hypoglycemia with such concentrations, even in diabetic patients.
- Dextrose should be administered to all patients with altered levels of consciousness and numerical hypoglycemia (glucose concentration <90 mg/dL).
- Dextrose should be empirically administered to patients with altered levels of consciousness in the rare cases where bedside reagent strips are not readily available.

A13 ANTIDOTES IN DEPTH

Octreotide

Mary Ann Howland and Silas W. Smith

INTRODUCTION

Octreotide is a long-acting, synthetic octapeptide analog of somatostatin that inhibits pancreatic insulin secretion. It currently is the essential complement to dextrose for the treatment of refractory hypoglycemia induced by overdoses of insulin secretagogues (eg, sulfonylureas) and quinine. Although not formally approved by the US Food and Drug Administration (FDA) for this indication, octreotide currently is used in toxicology for the treatment of hypoglycemia from insulin secretagogues.

HISTORY

Somatostatin is a collective term for shorter fragments (SRIF-28, SRIF-25, and SRIF-14) cleaved by tissue specific enzymes from preprosomatostatin (116 amino acids) and prosomatostatin (92 amino acids).¹⁴ Somatostatin was identified in 1973, during the search for growth hormone releasing factor.⁸ In addition to its effects on growth hormone and insulin secretion, somatostatin has far-reaching effects as a central nervous system (CNS) neurotransmitter and as a modulator of hormonal release.^{45,54} The importance of somatostatin on insulin secretion led to the need to create an analog as a therapeutic tool as somatostatin is limited because of its short duration of action.

Octreotide was synthesized in 1982 in an effort to develop a longer-acting analog of somatostatin.⁵ Octreotide is currently approved by the FDA for the treatment of acromegaly, carcinoid tumors, and vasoactive intestinal peptide tumors. It is also used therapeutically for the treatment of pituitary adenomas, pancreatic islet cell tumors, portal hypertension, esophageal varices, and secretory diarrhea.⁴⁵ Octreotide is being investigated for its inhibitory effects on tumor cell proliferation through stimulation of apoptosis, antiangiogenesis, immunomodulatory effects, and the suppression of tumor-stimulating growth factors.^{42,45,55}

PHARMACOLOGY

Mechanism of Action on Insulin Secretion and Other Hormones

The effects of somatostatin are mediated by high-affinity binding to membrane receptors on target tissues. Five different somatostatin receptor subtypes that belong to a superfamily of G-protein coupled receptors are identified and assigned numbers (SSTR1–SSTR5) according to their order of discovery.¹⁴ Octreotide, lanreotide, and vapreotide have high binding affinity for subtype SSTR2, a lower affinity for SSTR5 and SSTR3, and almost no affinity for SSTR1 and SSTR4.⁴⁵ The pancreas contains all five subtypes, but in mice SSTR5 is more prevalent in the β -cells and SSTR2 is more prevalent in the α -cells in animal studies.⁶⁹ SSTR5 is found in many tissues, including the brain, pituitary, stomach, intestine, thyroid, and adrenal gland; SSTR2 is found in the brain, pituitary, stomach, liver, kidney, lung, intestine, spleen, thymus, uterus, prostate, and adrenal gland.^{45,50,58,69} A variety of pituitary and gastroenteropancreatic tumors contain varying percentages of the SSTR subtypes. Recently in comparison to studies in mice SSTR2 was found to be the functionally dominant somatostatin

receptor in human pancreatic β - and α -cells.³⁶

Octreotide, similar to the natural hormone somatostatin, but with a longer duration of action, is a potent inhibitor of growth hormone, glucagon, and insulin. It also suppresses the response of luteinizing hormone to gonadotropin releasing hormone; decreases splanchnic blood flow; and inhibits the release of serotonin, gastrin, vasoactive intestinal peptide, secretin, motilin, thyroid-stimulating hormone, and pancreatic polypeptide.⁵⁴

Experiments in both healthy human volunteers and an isolated perfused canine pancreas model demonstrate the ability of somatostatin to inhibit glucose-stimulated insulin release.^{2,26} Experiments using a whole-cell patch clamp technique on a hamster β -cell line suggest that somatostatin inhibits insulin secretion by a G-protein-mediated decrease in calcium entry through voltage-dependent Ca^{2+} channels.³⁴ No evidence indicates that somatostatin inhibits insulin release by promoting K^{+} efflux through K_{ATP} channels at physiologic concentrations as do the oral hypoglycemics (Fig. 53–2).^{22,47,56} Instead somatostatin, like epinephrine, stimulates a pertussis toxin sensitive Gi-coupled receptor that inhibits adenylate cyclase and production of cyclic adenosine monophosphate (cAMP), decreasing intracellular calcium and thereby reducing insulin secretion.³² Simultaneous distal reduction in phosphorylation of specific proteins may also be involved in reducing insulin secretion.^{22,32,43} This latter mechanism appears to be independent of Ca^{2+} .^{22,32} More recent experiments in human pancreatic β - and α -cells indicate somatostatin agonism via SSTR2 hyperpolarizes human β -cells and decreases depolarized evoked exocytosis in both α - and β -cells via several mechanisms.³⁶ First, increased current through G-protein gated inward rectifying potassium (GIRK, Kir3.x) channels can be demonstrated. This effect is independent of the ATP-sensitive K^{+} (K_{ATP}) channel, and thus it remains effective when the K_{ATP} channel is antagonized by an oral sulfonylurea. Second, somatostatin inhibits a depolarization leak current (mediated by an as yet unidentified channel). Third, somatostatin reduced voltage-gated P/Q-type Ca^{2+} currents. Lastly, somatostatin directly inhibited calcium dependent exocytosis.

Activation of SSTR5 on the β -cell of the pancreas also reduces insulin biosynthesis.²² One study in human volunteers confirms the ability of somatostatin to inhibit the increased insulin response to both glucose and glucagon.²⁶ Intravenous (IV) infusion of 1 g of tolbutamide over 2 minutes caused insulin concentrations to rise and serum glucose concentration to drop sharply. Similarly, in the presence of somatostatin and tolbutamide, administration of IV glucagon caused a rise in glucose concentration without the expected subsequent glucose stimulated rise in insulin. The effects of somatostatin were short lived. Within 5 minutes of stopping the somatostatin, the insulin releasing effects of tolbutamide continued, and within 15 minutes the serum glucose concentration fell. Peak insulin concentrations were achieved within 25 minutes.

Studies comparing octreotide to somatostatin in rats and monkeys demonstrate that octreotide is 1.3 times as potent as somatostatin in inhibiting insulin secretion by 50%. Likewise, compared with somatostatin, octreotide was 45 times more potent in inhibiting growth hormone secretion and 11 times more potent in inhibiting glucagon release.⁷ Comparable results were found using a hyperglycemic glucose clamp technique.³⁹ Octreotide blocks the counterregulatory response to the effects of 0.1 unit/kg IV insulin by preventing an increase in glucagon and growth hormone. The effects of octreotide on the responses of adrenocorticotropin, cortisol, prolactin, luteinizing hormone, and follicle-stimulating hormone to insulin-induced hypoglycemia all remained intact.⁴⁷ In contrast, growth hormone²⁰ and thyroid stimulating hormone are significantly inhibited.⁴⁷

Related Xenobiotics. Lanreotide and vapreotide are very long-acting, FDA approved somatostatin analogs. However, their use in sulfonylurea induced insulin secretion is not warranted based on the time action profiles of the sulfonylureas.

Pharmacokinetics

The pharmacokinetics of IV and subcutaneous (SC) octreotide were studied in eight healthy adult volunteers.⁴¹ Subjects received 25, 50, 100, and 200 μg IV octreotide over 3 minutes and 50, 100, 200, and 400 μg SC octreotide in random order. Following IV administration, the distribution half-life averaged 12 minutes, and the elimination half-life ranged from 72 ± 22 minutes to 98 ± 37 minutes and was linear. V_i (volume of distribution of the central compartment) was dose dependent and increased from approximately 5.7 L at 25, 50, and 100 μg IV to 10 L at 200 μg IV doses.⁴¹ The V_d (volume of distribution determined by area under the curve) ranged from 18 ± 6 L to 30 ± 30 L and showed no dose dependency.⁴¹ Approximately 30% of elimination was renal, and this was reduced in the elderly and in those with chronic kidney disease.⁵⁴

After SC administration, bioavailability was 100%, and peak concentrations were achieved within 30 minutes with an absorption half-life of 5 to 12 minutes. The elimination half-life was 88 to 102 minutes. Peak serum concentrations after SC administration ranged from 2.4 ng/mL at doses of 50 μg to 23.5 ng/mL at doses of 400 μg . After IV administration, peak serum concentrations ranged from 9.6 ng/mL at doses of 50 μg to 27.8 ng/mL at doses of 200 μg .⁴¹

The pharmacokinetics in patients with pathologic conditions may differ from the pharmacokinetics in healthy volunteers as exemplified by a lower peak concentration and a higher steady state V_d in patients with acromegaly.⁵⁴ In patients with reduced kidney function and those with liver cirrhosis and fatty liver disease, the half-life ranges from 2.5 to 3.7 hours depending on the extent of impairment. The half-life in the elderly is also prolonged by about 50%.⁵⁴

Pharmacodynamics

The duration of action of octreotide is variable. When used for tumor suppression, the duration may last up to 12 hours.⁵⁴ The duration of action for inhibition of insulin secretion is unknown but presumed to be somewhere between 6 to 12 hours.

ROLE OF OCTREOTIDE FOR INSULIN SUPPRESSION

Controlled studies in animals given oral gliclazide demonstrate that a single dose of octreotide 50 µg or 100 µg SC results in fewer hypoglycemic events and dextrose boluses.³¹ Octreotide has been studied in humans in several clinical conditions, including insulinomas and hypoglycemia of infancy.^{3,27,37,65,67} In most instances, octreotide suppressed insulin concentrations and glucose concentrations rose. However, worsening hypoglycemia has been reported when suppression of α cell glucagon release outlasts suppression of β cell insulin release.^{8,13,25,33,53,65} Another reason for variable effects in these conditions includes the absence of octreotide-susceptible SSTR receptor subtypes.¹⁹ Octreotide currently is used in toxicology for treatment of hypoglycemia from insulin secretagogues.

In controlled studies of healthy volunteers, octreotide suppressed the release of insulin associated with quinine.⁶¹ Life-threatening hypoglycemia is a well-recognized complication of quinine treatment of *Plasmodium falciparum* malaria; quinine blocks the K_{ATP} channel in an analogous manner to sulfonylureas.⁹ In this setting, hypertonic dextrose and diazoxide therapy are frequently inadequate, with ensuing refractory hypoglycemia. In an investigation of the potential hypoglycemia sparing effect of octreotide given for treatment of quinine induced hypoglycemia, healthy adults were given 50 µg/h octreotide or placebo as a continuous IV infusion for 4 hours, followed at the first hour by infusion of 490 mg quinine base.⁶⁰ In the control subjects, serum insulin concentrations rose and serum glucose concentrations fell significantly, whereas in the octreotide group, insulin concentrations fell and glucose concentrations remained constant. This effect of octreotide began within 30 minutes and persisted for 2 hours after octreotide was stopped. Octreotide was used successfully to treat refractory hypoglycemia in a woman receiving 600 mg quinine dihydrochloride IV for malaria.⁶⁰ A subsequent treatment study⁶¹ confirmed these findings and noted that its volunteer arm, a single 100 µg dose suppressed quinine induced hypoglycemia within 15 minutes. Because quinolone antibiotics share a 4-quinolone nucleus with quinine, they are also associated with rare hypoglycemia due to K_{ATP} inhibition.⁴⁶ Octreotide has been used to reverse quinolone associated hypoglycemia.³⁸

Octreotide efficacy for sulfonylurea-induced hypoglycemia was demonstrated in an early experimental study. Eight healthy volunteers were given 1.43 mg/kg glipizide orally and randomized to receive either a variable dextrose infusion to remain euglycemic, diazoxide 300 mg IV over 30 minutes and repeated every 4 hours with dextrose, or octreotide 30 ng/kg/min IV continuously.¹⁰ Following administration of glipizide, hypoglycemia of 50 mg/dL was achieved within 30 to 165 minutes.¹⁰ Insulin concentrations in the diazoxide group were comparable with those in the glipizide group and were four to five times higher than in the octreotide group. Four of the eight patients in the octreotide group did not require supplemental dextrose. At the fifth hour of the protocol, an IV bolus of 50 mL of 50% dextrose was given to the octreotide group to study the response to hyperglycemia. Approximately 6.5 hours was necessary for the serum glucose concentration to drop to 85 mg/dL, whereas only 3 hours was necessary in the dextrose and diazoxide groups.¹⁰ This demonstrates that octreotide can suppress the ability of hyperglycemia to result in the endogenous release of insulin. Diazoxide infusion was associated with higher norepinephrine concentrations, while epinephrine concentrations were similar in all groups.¹⁰ All xenobiotics were stopped at 13 hours, and serum glucose concentrations fell to less than 65 mg/dL within 1.5 hours in subjects who received the dextrose and diazoxide, whereas the serum glucose concentrations remained greater than 65 mg/dL in six of the eight octreotide subjects for the 4 hour observation period. Without additional octreotide, hypoglycemia recurred for as long as 30 hours after the initial glipizide administration. One prospective, randomized controlled trial of 40 hypoglycemic, poisoned patients (using a single octreotide 75 µg dose subcutaneously) demonstrated consistently higher glucose values for the duration for which octreotide would be expected to be effective (6–8 hours).²³ The failure to control for carbohydrate intake and combined exposure to insulin complicate interpretation of the results.

Many case studies, two case series of 15 patients, and recent reviews^{15,21,28} support the efficacy of octreotide following overdoses of glipizide, glyburide, gliclazide, glimepiride, tolbutamide, and nateglinide. These cases encompass both intentional and unintentional overdoses in children and adults with and without diabetes.^{10,12,16–18,24,29,30,35,39,48,51,52,59,63,68} In these case reports, therapeutic doses ranged considerably, and the most frequent doses were 50 to 100 µg subcutaneously repeated every 8 to 12 hours in the adult patients and 1 to 2 µg/kg SC or IV as a starting dose in pediatrics and repeated every 6 hours as needed.^{15,28}

ADVERSE EFFECTS AND SAFETY ISSUES

Octreotide is generally well tolerated, but toxicologic experience is limited. Adverse reactions occurring with short term

administration usually are local or gastrointestinal (nausea, abdominal cramps, diarrhea, fat malabsorption, and flatulence).⁴⁵ Stinging at the injection site occurs in approximately 7% of patients but rarely lasts more than 15 minutes.⁷⁰ Healthy volunteers receiving octreotide noted no side effects when given IV doses of 25 or 50 µg or SC doses of 50 or 100 µg. At higher doses, early transient nausea and later appearing but longer lasting diarrhea and abdominal pain frequently occur.^{40,41} Healthy volunteers were given IV bolus doses of octreotide as high as 1000 µg and infusion doses of 30,000 µg over 20 minutes and 120,000 µg over 8 hours without serious adverse effects. Single doses in healthy volunteers resulted in decreased biliary contractility and bile secretion.⁵⁴ Long term therapy lasting weeks to months results in biliary tract abnormalities.^{54,71} Octreotide use to reverse sulfonylurea induced hypoglycemia has rarely resulted in bradycardia, hypokalemia, anaphylactoid reactions, hypertension, and apnea.^{18,66} Product information suggests the potential for acute cholecystitis, ascending cholangitis, biliary obstruction, cholestatic hepatitis, and pancreatitis.⁵⁴

Octreotide alters the balance among insulin, glucagon, and growth hormone. Serum glucose concentrations must be serially monitored. Hyperglycemia often occurs, but cases of hypoglycemia are reported. A revision in the precautions section of the package labeling states that symptomatic hypoglycemia occurs in patients with type I diabetes and their insulin requirements will likely be reduced. The most likely explanation is suppression of counterregulatory hormones, in particular when glucagon suppression, is more persistent than insulin suppression.⁵⁴

Other adverse effects reported with long-term administration of octreotide or for octreotide in circumstances other than sulfonylurea-induced hypoglycemia include hypothyroidism, cardiac conduction abnormalities, worsening congestive heart failure and QT prolongation (in at-risk patients with acromegaly), bradycardia, pancreatitis, substantial hyperglycemia and bradycardia in an infant with congenital hyperinsulinemia, hypoxemia and pulmonary hypertension in premature neonates, necrotizing enterocolitis,⁴⁴ altered fat absorption, hyperkalemia in a hemodialysis patient,¹ and decreased vitamin B₁₂ concentrations.^{4,6,54}

Drug interactions are expected with xenobiotics that affect glucose regulation. Octreotide may significantly decrease oral absorption of cyclosporine and increase the bioavailability of bromocriptine. Because octreotide may suppress the activity of the cytochrome P450 enzymes, in particular CYP3A4, drugs with narrow therapeutic indices metabolized by these enzymes should be monitored more closely.⁵⁴

PREGNANCY AND LACTATION

Octreotide is considered a category B drug. Pregnant women must be carefully monitored for recurrent hypoglycemia. Use of octreotide should not diminish this vigilance. Studies in breastfeeding have not been performed.

DOSING AND ADMINISTRATION

No controlled trials have evaluated the optimal dose of octreotide for the management of sulfonylurea overdose. In adults, a 50 µg SC dose of octreotide given every 6 hours is suggested. In children, a dose of 4 to 5 µg/kg/d SC divided every 6 hours, up to the adult dose, can be used for initial therapy. This pediatric dose is derived from the literature on treatment of persistent hyperinsulinemic hypoglycemia of infancy.²⁷ In situations where compromised peripheral blood flow is expected, octreotide should be administered IV in the same dose but every 4 hours instead of every 6 hours. An increase in the dose is rarely required. Further toxicologic experience should permit a better delineation of dosing recommendations.

While the optimal duration of octreotide therapy awaits definitive study, several principles and patient factors help guide management. First, the duration of action of every single sulfonylurea except tolbutamide exceeds 12 hours, and this might be altered with extended-release formulations, sulfonylureas with enterohepatic recirculation, in overdose, and with coingestions or coadministrations.^{23,59,62} Second, the onset of hypoglycemia may be significantly delayed following ingestion (as late as 21 to 48 hours, depending upon the hypoglycemic).^{57,64} Third, acute or chronic kidney dysfunction (whether intrinsic or secondary to insufficient perfusion as in cases of congestive heart failure), which may have predisposed to sulfonylurea induced hypoglycemia in the first place, alters elimination of both oral sulfonylureas and antidotal octreotide. Fourth, a controlled animal study demonstrated the failure of single dose octreotide to eliminate recurrent late (9–24 hour) hypoglycemic episodes.³¹ Fifth, human data suggest potential inadequacy of single or few octreotide doses. In one case series, failure occurred 14 hours after a patient's last dose of octreotide (more than 30 hours after the ingestion of glyburide), and an additional failure occurred 36 hours after a single dose of octreotide (40 hours after ingestion of extended-release glipizide).⁴⁸ In humans administered glipizide, after 13 hours of continuously provided octreotide therapy, two of eight subjects (25%) had decreases in glucose more than 3 hours after stopping octreotide. Without ongoing octreotide, hypoglycemia persisted for as long as 30 hours and hyperinsulinemia persisted for greater than 16 hours after the initial glipizide administration.¹⁰ Treatment failures (episodes of glucose <60 mg/dL) occurred in 10 of 22 patients (45%) in a prospective, randomized controlled employing a single-dose octreotide strategy; two events occurred at 12 and 13 hours after octreotide administration.²³ Thus, although one or two octreotide doses might prove

adequate, the available pharmacokinetic, animal, and human data suggest that this may be insufficient, and several days of therapy may be required, depending on the particular xenobiotic, quantity of ingestion, coingestants, and individual patient factors. All patients must be carefully monitored for recurrent hypoglycemia during octreotide therapy and for 12 to 24 hours following termination of octreotide therapy before discharge.¹⁰ The potential for unrecognizable recurrent hypoglycemia during sleep necessitates that patients must not be discharged during the high risk circadian phase (eg, evening or night), unless the patients have been monitored for an adequate amount of time off of octreotide and after a dextrose challenge (which may increase the release of insulin). Other patients at risk for hypoglycemia unawareness (defective glucose counterregulation and hypoglycemia without warning symptoms)⁵ should also be managed conservatively.

Both SC and IV administration are acceptable, although the usual route is SC.⁵⁴ The SC administration sites should be rotated. For IV infusion, octreotide can be diluted in sterile 0.9% sodium chloride solution or D₅W and infused over 15 to 30 minutes or by IV bolus over 3 minutes.⁵⁴ Rapid IV bolus may be indicated for carcinoid crisis.⁵⁴

Refrigeration of octreotide is recommended for prolonged storage, although octreotide is stable at room temperature for 14 days when protected from light. Active warming of refrigerated octreotide is not recommended, although passive warming to room temperature prior to administration is suggested and may reduce the pain of SC administration.⁴⁹

Using the smallest volume possible also reduces the pain with SC administration. A depot formula designed to last for 4 weeks is available (Sandostatin LAR Depot). Although the depot formula is useful for patients with insulinomas, its duration of action far exceeds that of any insulin secretagogue, making it an inappropriate and unnecessary choice for management of xenobiotic-induced hypoglycemia. Vapreotide (Sanvar IR) and lanreotide (Somatuline Depot) are analogs of somatostatin that are available in the United States but are inappropriate for use in the setting of xenobiotic induced insulin secretion.

FORMULATION AND ACQUISITION

Octreotide acetate (Sandostatin) injection is available in ampules and multidose vials ranging in concentration from 50 to 1000 µg/mL. The multidose vials contain phenol. It should not be confused with the long-acting formulation—Sandostatin LAR.

SUMMARY

- The available evidence indicates that octreotide is useful for preventing the reoccurrence of hypoglycemia induced by the insulin secretagogues sulfonylureas and quinine that cause endogenous release of insulin.
- Octreotide is more effective than diazoxide in suppressing insulin release and is better tolerated.
- Octreotide is not a substitute for IV dextrose for the immediate treatment of hypoglycemia or and does not decrease the need for frequent glucose assessments.
- Before discharge, the following should be ensured: the effects of octreotide have dissipated, the patient remains euglycemic following an adequate oral dextrose challenge, and there has been a sufficiently prolonged observation time since ingestion to ensure that hypoglycemia will not occur in a fasting or sleeping patient.

54 ANTIMIGRAINE MEDICATIONS

Jason Chu

PATHOPHYSIOLOGY OF MIGRAINE HEADACHES

A migraine headache is a neurovascular disorder often initiated by a trigger and characterized by a headache, which is preceded by a visual aura 20% of the time. The headache may be accompanied by a variety of multiple organ system symptoms, such as allodynia, nausea, vomiting, and urinary frequency. There are various types of migraine, the diagnostic criteria for which are established by the International Headache Society.⁴ The types of migraine are divided into two groups: migraine without aura (“common migraine”) and migraine with aura (“classic migraine”). Further subdivisions include migraine with typical aura with or without headache, familial hemiplegic migraine, sporadic hemiplegic migraine, basilar type migraine, and retinal migraine.⁴

The initiation of migraines is not fully understood, but likely involves genetic abnormalities in central nervous system (CNS) ion channels that predispose patients to specific triggers. Patients with familial hemiplegic migraine, an autosomal dominant disorder, have missense mutations in the α_1 subunit of brain specific P/Q voltage-gated calcium channels resulting in altered function of these channels. During migraines, the upper brainstem has increased blood flow and is implicated as a “migraine generator.” After activation, a wave of cortical depression spreads across the cortex from a caudal to rostral fashion followed by a spreading wave of oligemia, which can produce the auras that occur in 20% of migraineurs.^{26,36,86} Current theories suggest that this spreading wave also occurs in patients who do not experience visual auras but spares the visual cortex.

Cephalalgia begins during vasoconstriction prior to vasodilation. Antidromic activation of the afferent neurons of the ophthalmic division of the trigeminal nerve and branches of the C1 and C2 nerves (first order neurons) located on dural arteries at the base of the brain releases inflammatory neuropeptides such as calcitonin gene-related polypeptide (CGRP), vasoactive intestinal peptide (VIP), and neurokinin A. Vasoactive neuropeptides, including serotonin, nitric oxide, substance P, neurokinin A, and calcitonin gene-related peptide (CGRP), are released during this process, which exacerbates the vasodilation and irritates the meninges at the base of the brain, causing further pain. CGRP from trigeminal A- δ -fibers produces dural vasodilation, while substance P and neurokinin A from trigeminal C-fibers increase dural vessel permeability.^{24,26} Pain impulses are relayed orthodromically to the trigeminal nucleus caudalis (second order neurons) in the lower medulla and upper cervical spinal cord, then to the thalamus (third order neurons) via the quintothalamic tract, and finally to higher cortical areas (fourth order neurons probably located in the limbic cortex).^{26,34} The trigeminocervical complex also produces retrograde parasympathetic impulses from the sphenopalatine ganglion and the superior salivatory nucleus in the pons through the pterygopalatine, otic, and carotid ganglia to the cerebral vessels.³⁴

Treatment of migraines encompasses a wide variety of xenobiotics that can be broadly classified as prophylactic or abortive therapies (Table 54–1). Current abortive therapies include analgesics (nonsteroidal antiinflammatory drugs, acetaminophen {APAP}, opioids), antiemetics, ergots alkaloids, triptans, oxygen, magnesium sulfate, and intranasal lidocaine. Triptans are considered the drugs of choice for abortive migraine therapy. Prophylactic therapies with the evidence for established efficacy include antiepileptics (topiramate, valproic acid), β -adrenergic antagonists (metoprolol, propranolol, timolol) and triptans (for menstrually related migraines).⁷⁵

TABLE 54–1. Xenobiotics Used in Migraine Treatment^a

<i>Prophylactic</i>	<i>Abortive</i>
β-Adrenergic antagonists	Acetaminophen
Antiepileptics: Gabapentin, lamotrigine, levetiracetam, topiramate, valproic acid, zonisamide	Antiemetics: metoclopramide, ondansetron, prochlorperazine
Antipsychotics: Aripiprazole, olanzapine, quetiapine	Aspirin
Benzodiazepines	Butalbital
Butterbur root	Butyrophenones: droperidol, haloperidol
Calcium channel blockers	Caffeine
Candesartan	Corticosteroids
Coenzyme Q10	Ergots
Cyclic antidepressants	Lidocaine (intranasal)
Cyproheptadine	Magnesium (intravenous)
Enalapril	Nonsteroidal antiinflammatory drugs
Feverfew	Opioids
Flunarizine	Oxygen
Hormonal contraceptives	Sedative-hypnotics
Isometheptene/dichloralphenazone/acetaminophen (Midrin)	Triptans
Lisinopril	Valproic acid
Magnesium (oral)	
Monoamine oxidase inhibitors	
Melatonin	
Memantine	
Nefazodone	
OnabotulinumtoxinA (Botox A)	
Pizotifen	
Riboflavin	
Selective serotonin reuptake inhibitors	

*Prophylactic xenobiotics are usually taken to prevent triggering of migraines, and abortive xenobiotics are usually taken to stop the clinical manifestations of migraines once they are triggered. However, the separation between the two groups of xenobiotics is not strict, and some xenobiotics may be used in both roles. Triptans are currently considered the drug class of choice for migraine treatment.

ERGOT ALKALOIDS

History and Epidemiology

Ergot is the product of *Claviceps purpurea*, a fungus that contaminates rye and other grains. The spores of the fungus are both windborne and transported by insects to young rye, where they germinate into hyphal filaments. When a spore germinates, it destroys the grain and hardens into a curved body called the sclerotium, which remains the major commercial source of ergot alkaloids.⁷¹ The *C. purpurea* fungus produces diverse substances, including ergotamine, histamine, lysergic acid, tyramine, isomylamine, acetylcholine, and acetaldehyde.

In 600 B.C. an Assyrian tablet mentioned grain contamination believed to be by *C. purpurea*. In the Middle Ages, epidemics causing gangrene of the extremities, with mummification of limbs, were depicted in the literature as blackened limbs resembling the charring from fire and caused a burning sensation expressed by its victims. The disease was called holy fire or St. Anthony's fire, but the improvement that reportedly occurred when victims went to visit the shrine of St. Anthony was probably the result of a diet free of contaminated grain on the journey.³⁷ Abortion and seizures were also reported to result from this poisoning. On the other hand, as early as 1582, midwives used ergot to assist in the childbirth process. In 1818, Desgranges was the first physician to use ergot for obstetric care, and in 1822 Hosack reported that ergot could be used for the control of postpartum hemorrhage.⁸⁴ Since 1950, the clinical use of ergot derivatives is almost entirely limited to the treatment of vascular headaches. Ergonovine, another ergot derivative, is used in obstetric care for its stimulant effect on uterine smooth muscle and was formerly used in cardiac stress tests. Methylergonovine is used for

postpartum uterine atony and hemorrhage. Cabergoline is used for hyperprolactinemia and in the treatment of Parkinson disease. Ergot derivatives were also used as “cognition enhancers,”⁸⁷ to help manage orthostatic hypotension,⁷⁸ and to prevent the secretion of prolactin.⁷¹

Currently in the US, human poisoning epidemics from ergot grain infestations are prevented by government inspections of grain fields. If a grain field contains more than 0.3% affected grain, then it is rejected for commercial sale; in some years, as much as 36% of the grain was rejected.⁷¹ However, elsewhere in the world ergot toxicity remains a problem predominantly in animals.^{9,48}

Pharmacology and Pharmacokinetics

All ergot alkaloids are derivatives of the tetracyclic compound 6-methylergoline. They can be divided into three groups: amino acid alkaloids (ergotamine, ergotoxine), dihydrogenated amino acid alkaloids, and amine alkaloids (Fig. 54–1).

FIGURE 54–1. Chemical structures of two ergot derivatives representative of the amine and amino acid alkaloids.

The pharmacokinetics of the ergot alkaloids are well defined by controlled human volunteer studies, whereas the toxicokinetics are essentially unknown (Table 54–2). Almost all of the ergots are poorly absorbed orally and there is considerable first-pass hepatic metabolism, resulting in highly variable bioavailability. Intramuscular absorption is unpredictable and actions are often delayed.⁶³ Peak plasma concentrations with oral ergotamine occur within 45 to 60 minutes.⁶³ The volume of distribution of ergotamine is approximately 2 L/kg and the half-life varies from 1.4 to 6.2 hours. Ergot alkaloids are metabolized in the liver, probably by CYP3A4, and the metabolites are excreted in the bile.^{7,71}

TABLE 54–2. Pharmacokinetics of Ergots

Ergot Derivative	Clinical Use	$t_{1/2}$ (hours)	Duration of Action (hours)	Bioavailability (%)	Metabolism/Elimination
Bromocriptine	Parkinsonism, amenorrhea/prolactinemia syndrome	60 (PO)	1 week (suppression of prolactin)	28 (PO)	Liver
Dihydroergotamine	Migraine	2.4	3–4 (IM)	100 (IM) 40 (Nasal) <5 (PO)	Liver metabolism Bile excretion
Ergonovine	Testing for coronary vasospastic angina	1.9	3	(IV) 100	Liver
Ergotamine	Migraine	2 (1.4–6.2)	22 (IV)	100 (IV) 47 (IM) <5 (PO)	Liver metabolism Bile excretion
Methylexgonovine	Postpartum hemorrhage	1.4–2.0	3	78 (IM) 60 (PO)	Liver
Methysergide	Migraine	2.7/10 hours (PO)	8–24	13 (PO)	Liver—metabolized to methylexgonovine

IM = intramuscular; IV = intravenous; PO = oral.

The pharmacologic effects of the ergot alkaloids can be subdivided into central and peripheral effects (Table 54–3). In the CNS, ergotamine stimulates serotonergic receptors, potentiates serotonergic effects, blocks neuronal serotonin reuptake, and has central sympatholytic actions.^{37,71} Ergotamine and dihydroergotamine interact with the 1A, 1B, 1D, 1F, 2A, 2C, 3, and 4 serotonin receptor subtypes, dopamine receptors and adrenergic receptors.⁸ The result is increased intrasynaptic serotonin activity in the median raphe neurons of the brainstem.⁶⁸ Ergotamine and dihydroergotamine decrease the neuronal firing rate and stabilize the cerebrovascular smooth musculature, which make them useful drugs for both abortive and prophylactic treatment of migraine headaches.

TABLE 54–3. Pharmacology of Ergot Derivatives

Ergot Derivative	Interactions with Tryptaminergic (Serotonergic) Receptors	Interactions with Dopaminergic Receptors	Interactions with α -Adrenergic Receptors
Bromocriptine (amino acid alkaloid)	Weak antagonist	CNS: Partial agonist/antagonist; inhibits prolactin secretion; emetic (high)	Vasculature: Antagonist
Dihydroergotamine (dihydrogenated group)	Smooth muscles: Partial agonist/antagonist CNS: Agonist lateral geniculate nucleus	CNS: Emetic (mild) Sympathetic ganglia: Antagonism	Vasculature: Partial agonist (veins); antagonist (arteries) Smooth muscles: Antagonism CNS/PNS: Antagonism
Ergonovine and methylexgonovine (amine alkaloid)	Smooth muscles: Potent antagonist Vasculature: Agonist in umbilical and placental vessels CNS: Partial antagonist/agonist	CNS: Emetic (mild); inhibits prolactin (weak); partial agonist/antagonist Vasculature: Weak antagonist	Vasculature: Partial agonist
Ergotamine (amino acid alkaloid)	Vasculature: Partial agonist Smooth muscles: Nonselective antagonist CNS: Poor agonist/antagonist	CNS: Emetic (potent)	Vasculature: Partial agonist/antagonist Smooth muscles: Partial agonist/antagonist CNS: Antagonist PNS: Antagonist
Methysergide (amine alkaloid)	Vasculature: Partial agonist CNS: Potent antagonist	None	None

CNS = central nervous system; PNS = peripheral nervous system.

Peripherally, ergotamine and dihydroergotamine are α -adrenergic, 5-HT_{2A} and 5-HT_{1B} agonists and vasoconstrictors.⁷⁶ The amino acid ergot alkaloids (ergotamine, ergotoxine) exhibit α -adrenergic agonism, and dehydrogenation

(dihydroergotamine) of the lysergic acid nucleus increases the potency of this effect.⁷¹ Ergotamine is a more potent constrictor of peripheral arteries, whereas dihydroergotamine is a more potent vasoconstrictor.¹⁶ Table 54–3 summarizes the pharmacologic actions of selected ergot alkaloids currently used in clinical medicine. The spectrum of effects depends on dose, host response, and physiologic conditions.

The clinical effects following overdose are an extension of the therapeutic effects. At toxic doses, extreme vasoconstriction produces the characteristic ischemic changes that occur in ergotism.

The cerebrovascular effects of ergot alkaloids are not as clearly understood. In migraine treatment, for example, therapeutic doses of ergotamine produce mild vasoconstriction via α -adrenergic agonism. This may be more pronounced in intracranial vessels that are already dilated during a migraine. In toxic doses, cephalic vasodilation may occur but the mechanism for this effect is unknown. One hypothesis is that toxic doses initially produce cerebral vasoconstriction and ischemia, just as occurs in the periphery, but since the cerebral vasculature cannot tolerate hypoxia and hypercapnia, rapid vasodilation then ensues to improve local perfusion. In addition, α -adrenergic receptors in the CNS function differently from those in the periphery, and it may be that CNS vascular tone cannot be maintained in the setting of local tissue hypoxia.

Clinical Manifestations

Ergotism, a toxicologic syndrome resulting from excessive use of ergot alkaloids, is characterized by intense burning of the extremities, hemorrhagic vesiculation, pruritus, formication, nausea, vomiting, and gangrene (Table 54–4). Headache, fixed miosis, hallucinations, delirium, cerebrovascular ischemia, and convulsions are also associated with this condition, which has been called “convulsive” ergotism.³⁷ Chronic ergotism usually presents with peripheral ischemia of the lower extremities, although ischemia of cerebral, mesenteric, coronary, and renal vascular beds are well documented.^{3,27,28,69,70} Ergotism can also result from interactions of ergot derivatives with CYP3A4 inhibitors such as macrolide antibiotics and protease inhibitors, which increase bioavailability of ergots.^{6,7}

TABLE 54–4. Clinical Manifestations of Ergotism

Central Effects	Peripheral Effects
Agitation	Angina
Cerebrovascular ischemia	Bradycardia
Hallucinations	Gangrene
Headaches	Hemorrhagic vesications and skin bullae
Miosis (fixed)	Mesenteric infarction
Nausea	Myocardial infarction
Seizures	Renal infarction
Twitching (facial)	
Vomiting	

The vascular effects ascribed to ergot alkaloids are complex and sometimes conflicting (Table 54–3). Subintimal and medial fibrosis, vasospasm, and arteriolar and venous thrombi (stasis related) are all reported.⁵⁶ Angiography can demonstrate distal, segmental vessel spasm with increased collateralization in patients with chronic ergotism. The coronary, renal, cerebral, ophthalmic, and mesenteric vasculature,⁷⁰ as well as the vessels of the extremities, may also be affected.⁷³ Neuropathic changes may be secondary to ischemia of the vasa nervorum.

Bradycardia is a characteristic effect of the ergot alkaloids, and is believed to be a reflex baroreceptor-mediated phenomenon associated with vasoconstriction, but a reduction in sympathetic tone, direct myocardial depression, and increased vagal activity may also be factors.⁷¹

Myocardial valvular abnormalities are reported with ergot alkaloids. Ergotamine, methysergide, pergolide, and cabergoline cause mitral and aortic valve leaflet thickening and immobility resulting in valvular regurgitation.^{29,69,90}

Treatment

The treatment for a patient with ergot alkaloid toxicity depends on the nature of the clinical findings. Gastric emptying should rarely be used, if at all, because vomiting is a common early occurrence, and the ingestion may be complicated by seizures. After an acute oral overdose, 1 g/kg of activated charcoal should be administered orally. If emesis is present, antiemetics such as ondansetron or metoclopramide should be administered intravenously to facilitate the administration of activated charcoal. In mild cases, characterized by minimal pain of the extremities, nausea, or headache, supportive measures such as hydration and analgesia are all that are needed. Patients who develop mild symptoms of vasospasm, such as dysesthesias and minimal ischemic pain of the digits, should be treated with immediate release nifedipine 10 mg every 8

hours orally.¹⁵ With more serious cases, severe peripheral vasoconstriction may produce ischemic changes that include angina, myocardial infarction, cerebral ischemia, intermittent claudication, and internal organ/mesenteric ischemia. Intravenous sodium nitroprusside at a starting dose of 0.5 µg/kg/min is recommended and should be titrated until resolution of vasoconstriction.^{3,12,62} Phentolamine should be considered as well. Immediate release oral nifedipine at a dose of 10 mg every 8 hours can be administered as a second line therapy. Methylprednisolone at a dose of 1 mg/kg was reported to reverse ergotamine induced lower extremity arterial vasospasm that was not responsive to sodium nitroprusside and heparin.⁶⁶

Heparin or low molecular weight heparins should be administered to prevent sludging and subsequent clot formation. Benzodiazepines should be used to treat seizures or hallucinations.

TRIPTANS

In 1974, investigations began on a new class of compounds that produced vasoconstrictive effects via 5-HT receptors. The first compound successfully used in this way was 5-carboxamidotryptamine (5-CT). When applied to an isolated dog saphenous vein, 5-CT caused potent venoconstriction and induced significant hypotension in vivo. The next compound developed, AH25086 [(3-2-aminoethyl)-N-methyl-1-H-indole-5-acetamide], also constricted saphenous veins in dogs but had more 5-HT receptor selectivity. AH25086 was effective against acute migraine in human volunteers, but further research was stopped because it was deemed less suitable for development in humans, possibly owing to the fact that it was highly polar, lipophobic, and unsuitable for oral use.^{41,72} In 1984, sumatriptan was synthesized and its clinical success led to the rapid development of six other triptans: almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan and zolmitriptan, and one triptan combination medication (sumatriptan/naproxen; Fig. 54-2; Table 54-5).

TABLE 54-5. Pharmacokinetics of Triptans

Triptan	<i>t</i> _{1/2} (hours)	Duration of Action (hours)	Lipophilicity	Bioavailability (%)	Metabolism/Elimination
Almotriptan	3.0–3.7	24	Unknown	70–80	CYP3A4, CYP2D6 MAO-A (minor)
Eletriptan	3.6–6.9	14–16	High	50	CYP3A4
Frovatriptan	25	24	Low	24–30	CYP1A2 Kidney
Naratriptan	4.5–6.6	Unknown	High	63–74	Kidney (major) P450
Rizatriptan	1.8–3.0	25	Moderate	40–45	MAO-A
Sumatriptan	2.0–2.5	4	Low	14 (PO); 96 (SC)	MAO-A
Zolmitriptan	1.5–3.6	18	Moderate	40–49	CYP1A2 MAO-A (minor)

MAO = monoamine oxidase; PO = oral; SC = subcutaneous.

FIGURE 54-2. Representative chemical structure of the triptans.

Pharmacology

The triptans are all primarily 5-HT_{1B} and 5-HT_{1D} receptor agonists and have less activity at 5-HT_{1A} and 5-HT_{1F} receptors³⁰ (Chap. 14). In the CNS, 5-HT_{1B} receptors are located on cerebral vessels.³⁵ Stimulation of these receptors results in cerebral vasoconstriction,¹⁷ reversing abnormal cerebral vasodilation. In contrast, the 5-HT_{1D} receptors are located presynaptically on trigeminal neurons, and act as “autoreceptors” to decrease neurotransmitter release from central trigeminal nerve terminals.⁴⁵ The triptans also inhibit dural neurogenic inflammation by preventing the release of

vasoactive neuropeptides from peripheral trigeminal nerves.^{58,74} Peripherally, triptans cause vasoconstriction systemically through the 5-HT_{1B} receptor^{19,52} (Fig. 54–3).

FIGURE 54–3. Mechanism of action of triptans. Vasoconstriction of intracranial [1] and peripheral [5] blood vessels via 5-HT_{1B} receptor agonism. Inhibition of vasoactive peptide release [2] from trigeminal nerve terminals at dural vessels via 5-HT_{1D} agonism. Modulation of nociceptive transmission to trigeminal nucleus caudalis [3] and thalamus [4].

Sumatriptan has poor oral bioavailability but good subcutaneous bioavailability (96%), and is therefore preferentially given by this route. The newer triptans differ substantially from sumatriptan with regard to oral bioavailability, plasma half-life, time to maximum effect, and recurrence rate of headaches. All triptans are pharmacodynamically similar but pharmacokinetically different (Table 54–5).

Clinical Manifestations

With appropriate therapeutic use, the common adverse effects associated with the triptans are less common and include nausea, vomiting, dyspepsia, flushing, and paresthesias.^{18,71} However, the most consequential adverse effects are chest pressure and vasoconstriction. Chest pressure symptoms are reported in up to 15% of sumatriptan users.^{11,65} Although triptans reduce coronary artery diameter by 10% to 15%, chest pressure symptoms are not believed to be secondary to cardiac ischemia. Alternate hypotheses for the chest pressure sensations include a generalized vasospastic disorder in migraineurs, esophageal spasm, bronchospasm, alterations of skeletal muscle energy metabolism, and central sensitization of pain pathways.²⁰ Although the triptans show some degree of coronary artery constriction in vitro, studies demonstrate, and hence recommendations state, that there is no need for routine stress tests in low-risk patients prior to therapy with triptans.^{21,51,83}

However, triptans can cause ischemia due to vasoconstriction. Therapeutic sumatriptan use is associated with myocardial ischemia and or infarction, dysrhythmias, renal infarction, splenic infarction, and ischemic colitis.^{1,5,14,46,53,59,61,64} Cephalic vasoconstriction is the desired effect of sumatriptan, but there are reports of strokes, hemorrhages, and infarctions.^{13,44,50,57} Extrapyramidal symptoms, such as akathisia and dystonia, may also occur.⁴⁹ Therapeutic use of other triptans has caused spinal cord infarction, renal infarction, myocardial infarction, ischemic colitis, and seizures.^{32,47,55,85,88}

Animal studies showed a wide margin of safety with oral sumatriptan. Subcutaneous administration of 2 g/kg of sumatriptan to rats was lethal. Death was preceded by erythema, inactivity, and tremor.⁴² Dogs survived 20 mg/kg and 100 mg/kg subcutaneous doses, but developed hind limb paralysis, erythema, tremor, salivation, and loss of vocalization.⁴¹ Reactions in other animals include seizures, inactivity, reduced respiratory rate, cyanosis, ptosis, ataxia, mydriasis,

salivation, and lacrimation.^{42,79}

Excessive triptan use is associated with vasoconstrictive adverse effects. A 43 year-old man who used 23 (25 mg) tablets of sumatriptan and 32 tablets of a combination preparation of isometheptene 65 mg, dichloralphenazone 100 mg, and APAP 325 mg over 7 days for headaches developed a left occipital infarction with a right hemianopsia. Digital subtraction angiography revealed segmental narrowing in multiple cerebral vessels. The hemianopsia and vessel findings resolved after cessation of the sumatriptan and Midrin and treatment with nicardipine.⁵⁷ A 35 year-old woman who used 300 mg of sumatriptan orally and 12 mg subcutaneously developed ischemic colitis.⁴⁰ Two patients who received four times and 10 times the recommended dose of naratriptan developed severe hypertension.⁶⁰ However, not all triptan overdoses result in toxicity. One 36 year-old man reportedly used 66 (6 mg) doses of sumatriptan subcutaneously over 4 weeks for his cluster headaches and had no adverse effects.⁸¹ The maximum recommended dosage of sumatriptan is 12 mg subcutaneously in a 24-hour period. Patients who took single doses of 100 to 150 mg of almotriptan did not have any adverse effects.²

In 2006, the US Food and Drug Administration (FDA) issued an alert, warning of an increased risk of serotonin toxicity with triptans used in combination with selective serotonin reuptake inhibitors (SSRIs) or selective serotonin-norepinephrine reuptake inhibitors. The alert was based on 27 cases reported to the FDA Adverse Events Reporting System between 1998 and 2002.²⁵ The cases involved triptan use in conjunction with SSRIs that were coded as serotonin syndrome or symptoms indicative of serotonin toxicity.⁷⁷ A case series of serotonin toxicity from migraine medications described three cases associated with sumatriptan use alone, sumatriptan with sertraline, and sumatriptan with methysergide, lithium, and sertraline.⁵⁴ Other medications that might precipitate serotonin toxicity when used in conjunction with triptans include monoamine oxidase inhibitors (Chaps. 73 and 75).

Treatment

Treatment of triptan-induced vasoconstriction is dependent on the route of exposure and the organ system affected. Decontamination is not feasible after subcutaneous exposures, but can be effective following overdose of oral preparations. Gastrointestinal decontamination should be performed with activated charcoal. Because vomiting is not as prominent with triptan exposure as with exposure to the ergot alkaloids, gastric emptying procedures, such as orogastric lavage, may be considered early, but only following massive ingestion. The oral forms of rizatriptan and zolmitriptan are formulated to dissolve on the tongue, limiting the effectiveness of gastrointestinal decontamination.

Many reported cases of triptan induced vasoconstriction compromise responded to intravenous hydration and analgesia.^{46,32} Triptan-associated myocardial ischemia should be treated with aspirin, heparin, and intravenous nitroglycerin.⁶⁴ Coronary angiography should be performed for transmural myocardial infarctions with ST segment elevations on electrocardiography.^{53,61}

ISOMETHEPTENE

Isometheptene is a mild vasoconstrictor marketed as a combination preparation (Midrin) that includes dichloralphenazone, a muscle relaxant, and APAP. It has indirect α - and β -adrenergic agonist effects as well as minor direct α -adrenergic agonist effects on the peripheral vasculature.⁸² When administered early during a migraine exacerbation, it is as effective as sumatriptan in relieving migraine headache.³¹ Cerebral vasoconstriction is reported after therapeutic and excessive isometheptene use.^{59,67} Autonomic dysreflexia, which presented as hypertension, headache, diaphoresis, and flushing, was also reported in a man with spinal cord injury who used isometheptene for treatment of a migraine headache.⁸⁹ Treatment of isometheptene-induced vasoconstriction should include discontinuation of the medication and reversal of the vasoconstriction with calcium channel blockers or vasodilators, such as sodium nitroprusside, nitroglycerin, or phentolamine.

CGRP ANTAGONISTS

During migraines, CGRP is among the many vasoactive peptides released from activated trigeminal nerves.³³ CGRP is a potent vasodilator¹⁰ and is involved in the transmission of nociceptive signals from cerebral vessels to the central nervous system.²² CGRP receptors are found in nerve fibers in cerebral and dural vessels and in multiple areas of the central nervous system postulated in migraine genesis—the cerebral cortex, periaqueductal gray, locus coeruleus, dorsal raphe nuclei, solitary tractus nucleus, spinal dorsal horn, dorsal root ganglia, and trigeminal ganglia.⁸⁰ Treatment of active migraine with sumatriptan decreased CGRP concentrations to normal.³³

Two CGRP antagonists were developed for migraine therapy—olcegepant and telcagepant—neither olcegepant nor telcagepant is available. Based on two high dosing administrations, olcegepant has a volume of distribution of 20 L in an adult with a terminal half-life of 2.5 hours and minor renal excretion.⁴³ Adverse events reported with olcegepant include

paresthesia, flushing, fatigue, headache, abdominal pain, diarrhea, flatulence, rhinitis, dry mouth, and abnormal vision.^{23,43} Adverse effects reported with telcagepant include nausea, dizziness, somnolence, dry mouth, fatigue, paresthesia, and asthenia.^{38,39} Systemic vasoconstrictive adverse effects did not occur in the phase 2 and 3 trials with either olcegepant or telcagepant.

SUMMARY

- Migraine therapies include many xenobiotics for prophylaxis or for abortive therapy. Triptans have supplanted ergots as the primary abortive treatment for patients with migraines.
- Ergots interact with multiple 5-HT, dopamine, and adrenergic receptors, which can cause severe vasoconstriction and end organ ischemia.
- Ergot and triptan induced peripheral ischemia should be managed with vasodilators, calcium channel blockers, and heparin anticoagulation.
- Triptans are more selective and interact only with 5-HT_{1B/D/F} receptors but can also cause peripheral vasoconstriction and end organ ischemia. Triptan induced myocardial ischemia should be treated with anticoagulation, nitrates, and coronary angiography for transmural infarctions.
- Triptan use in conjunction with other serotonin increasing xenobiotics can increase the risk of serotonin toxicity.

55 PHARMACEUTICAL ADDITIVES

Sean P. Nordt and Lisa E. Vivero

HISTORY AND EPIDEMIOLOGY

During the last century there were several outbreaks of toxicity in the United States associated with pharmaceutical additives ([Chap. 2](#)). The 1937 Massengill sulfanilamide disaster is the most notorious of these epidemics. Diethylene glycol, an excellent solvent and potent nephrotoxin, was substituted for the additives propylene glycol and glycerin in the liquid formulation of a new sulfanilamide antibiotic because of lower cost.^{25,62,69} As a result, more than 100 people died from acute kidney failure.²⁵ Outbreaks of acute kidney failure occurred when diethylene glycol was used to solubilize acetaminophen in South Africa, Bangladesh, Nigeria, and Haiti, cough syrup in Panama, and teething powder in Nigeria.^{20,28,30,71,81,122,133}

In December 1983, a new parenteral vitamin E formulation (E-Ferol) was introduced. It contained 25 units/mL of α -tocopherol acetate, 9% polysorbate 80, 1% polysorbate 20, and water for injection. At the time, no premarketing testing was required for new formulations of an already approved drug. Several months after its release, a fatal syndrome in low-birth-weight infants, characterized by thrombocytopenia, acute kidney injury, cholestasis, hepatomegaly, and ascites, was described.^{1,109} Thirty-eight deaths and 43 cases of severe symptoms were attributed to E-Ferol. Vitamin E was thought to be the cause and E-Ferol was recalled from the market 4 months after its release. It is now believed that the polysorbate emulsifiers were responsible.¹

Although these additive-related occurrences are rare, relative to the frequency of pharmaceutical additive use, they illustrate the potential of pharmaceutical additive toxicity.

Pharmaceuticals are labeled specifically to focus attention on the active ingredient(s) of a product, thus giving the misimpression that additive ingredients are inert and unimportant. Additives, or excipients as they are more properly termed, are necessary to act as vehicles, add color, improve taste, provide consistency, enhance stability and solubility, and impart antimicrobial properties to medicinal formulations. Although it is true that most cases of excipient toxicity involve exposure to large quantities, or to prolonged or improper use, these adverse events are nonetheless related to the toxicologic properties of the excipient.

Prior to selecting the specific additives and quantity necessary for a drug formulation, the drug manufacturer must consider several factors, including the active ingredient's physical form, its solubility and stability, the desired final dosage form and route of administration, and compatibility with the dispensing container materials. The same active ingredient may require different excipients to impart appropriate pharmacokinetic characteristics to different dosage forms, such as in long-acting and immediate-release formulations. Similarly, multiple-dose injection vials containing the same active ingredients as single dose vials specifically require the addition of a bacteriostatic xenobiotic not necessary for single dose vials.

Unlike requirements for active ingredients, there is no specific US Food and Drug Administration (FDA) approval system for pharmaceutical excipients. As such, the FDA determines the amount and type of data necessary to support the use of a specific excipient on a case by case basis. Under current practice, only excipients that were previously permitted for use in foods or pharmaceuticals are defined as generally recognized as safe (GRAS), or "GRAS listed." All components of a pharmaceutical product, including excipients, must be produced in accordance with current good manufacturing practice standards to ensure purity. The Safety Committee of the International Pharmaceutical Excipients Council developed guidelines for the toxicologic testing of new excipients.¹⁶¹ Because of patent protection laws, it was not until very recently that manufacturers were required to provide a list of inactive ingredients contained in all pharmaceutical products. Although it is becoming easier to identify pharmaceutical additives in products, information on their effects and the mechanisms by which they cause adverse responses are often unknown or difficult to obtain.

This chapter summarizes the available literature on commonly used additives associated with direct toxicities ([Table 55–1](#)). Data on pharmacokinetics and mechanism of toxicity are presented where data are available. Although many additives are associated with hypersensitivity reactions, including anaphylaxis, these are not discussed because of their nonpharmacologic basis. However, excipients should always be considered as possibly causative in patients who develop hypersensitivity reactions.

BENZALKONIUM CHLORIDE

Benzalkonium chloride (BAC, BAK), or alkyldimethyl (phenylmethyl) ammonium chloride, is a quaternary ammonium cationic surfactant composed of a mixture of alkyl benzyl dimethyl ammonium chlorides. Although it is the most widely used ophthalmic preservative in the United States, it is also considered the most cytotoxic ([Table 55–2](#)).^{87,94} Benzalkonium chloride is also used in otic and nasal formulations, and in some small-volume parenteral preparations. The antimicrobial activity of BAC includes Gram-positive and Gram-negative bacteria, and some viruses, fungi, and protozoa. Because of its rapid onset of action, good tissue penetration, and long duration of action, BAC is preferred over other preservatives. The concentration of BAC in ophthalmic medications usually ranges from 0.004% to 0.01%.⁹⁴ Strong BAC solutions (> 0.1%) can be caustic ([Chap. 106](#)).

TABLE 55–2. Benzalkonium Chloride Concentrations of Common Ophthalmic Medications

<i>Medication</i>	<i>Percent</i>
Apraclonidine	0.01
Artificial tears	0.005–0.01
Betaxolol	0.01
Brimonidine/timolol	0.005
Carteolol	0.005
Ciprofloxacin	0.006
Cyclopentolate	0.01
Dexamethasone	0.02
Dorzolamide/timolol	0.075
Epinephrine	0.01
Gentamicin	0.01
Ketorolac	0.006
Levobunol	0.004
Naphazoline	0.01
Ofloxacin	0.005
Phenylephrine	0.005–0.01
Pilocarpine	0.01
Polymyxin B sulfate/trimethoprim	0.004
Tetrahydrozoline	0.01–0.02
Timolol	0.05–0.01
Tobramycin	0.01
Tropicamide	0.01

Ophthalmic Toxicity

Corneal epithelial cells harvested from human cadavers within 12 hours of death were exposed to a medium containing 0.01% BAC.¹⁵⁸ The surfactant properties of BAC resulted in intracellular matrix dissolution and loss of epithelial superficial layers. Following exposure to the medium, mitotic activity ceased and degenerative changes to corneal epithelium were noted. During a 24-hour observation period, epithelial cell cytokinetic or mitotic activity did not occur. Patients with compromised corneal epithelia may be at increased risk for the adverse effects of BAC.¹⁵⁸

Two case reports demonstrate the potential toxicity of BAC and highlight the difficulty of diagnosing BAC toxicity. A 36 year-old woman complained of decreased vision when she inadvertently switched from Lensrins, a contact lens cleaning solution, to Dacriose, an isotonic boric acid solution preserved with BAC. After 3 days, she had inflammation, pain, and decreased visual acuity. Examination of the cornea revealed many superficial punctate erosions of the epithelium. An in vitro experiment identified significant binding of BAC to soft contact lenses.⁵⁷ In the second case, a 56 year-old man diagnosed with keratoconjunctivitis sicca was treated with topical antibiotics and artificial tears containing BAC. Following one year of continual use, the patient developed intractable pain, photophobia, and extensive breakdown of the corneal epithelium. Not suspecting the BAC containing products, the patient continued to use the artificial tears solution for another 9 years despite continued pain and decreasing visual acuity. Replacement with a preservative free saline solution resulted in resolution of pain, photophobia, and corneal changes.⁹⁴ Furthermore, there are newer ophthalmic medication preservatives available (eg, polyquaternium-1, stabilized oxychloride complex, sodium perborate, Sof Zia), which appear to be less toxic than BAC and may ultimately replace BAC.⁴

A case series of corneal endothelial injury following the inadvertent intraocular use of balanced salt solution (BSS) preserved with BAC instead of preservative free BSS in 12 patients undergoing phacoemulsification, a surgical technique to remove cataract lenses. The BSS, was instilled in the anterior chamber. The operating room had run out of preservative free BSS and, unbeknownst to the surgeon, it was replaced with the BAC containing BSS, which contained 0.013% BAC. This is in excess of recommended concentration for intraocular use and is associated with corneal endothelial injury and edema. Within 48 hours of instillation of the BSS, the visual acuity in all 12 patients was limited to only being able to count fingers at two feet. This persisted in 11 of the patients at a 6 month follow-up evaluation after the instillation of the BSS. One patient did have improvement at 6 months of visual acuity to 20/120 and 20/30 without and with pinholes, respectively.⁹⁶

Nasopharyngeal and Oropharyngeal Toxicity

Human adenoidal tissue was exposed to oxymetazoline nasal spray preserved with BAC at concentrations ranging from 0.005 to 0.15 mg/mL for 1 to 30 minutes.¹⁵ Irregular and broken epithelial cells occurred at all concentrations; however, these findings developed earlier and more frequently with the higher concentrations. The number of beating ciliary bodies also decreased as the duration and the concentrations increased. Benzalkonium chloride may decrease the viscosity of the normal protective mucous lining of the naso- and oropharynx, resulting in cytotoxicity.

Administration of one of three nasal corticosteroid sprays, beclomethasone dipropionate, flunisolide, budesonide, preserved with either 0.031% or 0.022% BAC in the right nostril of rats twice daily for 21 days caused squamous cell metaplasia and a decrease in the number of goblet cells, cilia, and mucus.¹⁶ No histologic changes occurred in rats receiving any of the preservative-free steroids or in tissue exposed to 0.9% sodium chloride solution administered into the left nostril as the control. Similarly, in another study, epithelial desquamation, inflammation, and edema occurred when 0.05% and 0.10% BAC was applied hourly to the nasal cavities of rats for 8 hours.⁹⁰ No lesions developed in the nasal cavities of rats receiving 0.01% BAC.

In an in vitro study, cultured human nasal epithelial cells were exposed to varying concentrations of BAC compared with another preservative, potassium sorbate (PS), with phosphate-buffered saline (PBS) as a control. Cell viability was greatly reduced at the higher concentrations of BAC compared with no decrease in cell viability in the PS or PBS groups. Additionally, at concentrations used clinically loss of microvilli, destruction of cell membranes, and poor cytoskeletal alignment demonstrated by electron microscopy occurred.⁷⁸

An in vitro study of human nasal mucosa exposed mucosa to either fluticasone or mometasone preserved with either BAC or PS at various concentrations with subsequent measure of ciliary beat frequency. While PS did not affect ciliary beat frequency at any concentration, BAC adversely affected ciliary beat frequency. At lower concentrations, BAC slowed ciliary beat frequency and brought it to standstill at higher concentrations.⁷⁹

BENZYL ALCOHOL

Benzyl alcohol (benzene methanol) is a colorless, oily liquid with a faint aromatic odor that is most commonly added to pharmaceuticals as a bacteriostatic agent (Table 55–3). In 1982, a “gasping” syndrome, which included hypotension, bradycardia, gasping respirations, hypotonia, progressive metabolic acidosis, seizures, cardiovascular collapse, and death, was first described in low-birth-weight neonates in intensive care units.^{21,64,101} All the infants had received either bacteriostatic water or sodium chloride solution containing 0.9% benzyl alcohol to flush intravenous catheters or in parenteral medications reconstituted with bacteriostatic water or saline.^{21,64} The syndrome occurred in infants who had received more than 99 mg/kg of benzyl alcohol (range, 99–234 mg/kg).⁶⁴ The World Health Organization (WHO) currently estimates the acceptable daily intake of benzyl alcohol to be not more than 5 mg/kg body weight.²³

TABLE 55–3. Benzyl Alcohol Concentration of Common Medications

Medication	Percent	Average Dose (mL) ^a
Amiodarone	2.0	0.42 ^b
Atracurium	0.9	0.03
Bacteriostatic saline for injection	1.5	—
Bacteriostatic water for injection	1.5	—
Bumetanide	1.0	0.03
Chlordiazepoxide	1.5	0.03
Diazepam	1.5	0.03
Enalaprilat	0.9	0.01
Etoposide	3.0	0.14
Glycopyrrolate	0.9	0.01
Lorazepam	2.0	0.02
Methotrexate	0.9	0.01
Midazolam	1.0	0.01
Prochlorperazine	0.75	0.01
Vecuronium	0.9	0.01

^aBased on dosage for a 70-kg person. ^bBased on 24-hour dosage.

Pharmacokinetics

In adults, benzyl alcohol is oxidized to benzoic acid, conjugated in the liver with glycine, and excreted in the urine as hippuric acid. Preterm babies have a greater ability to metabolize benzyl alcohol to benzoic acid than do term babies, but are unable to convert benzoic acid to hippuric acid, possibly because of glycine deficiency. This results in the accumulation of benzoic acid (Fig. 55–1).⁶⁴ A fatal case of metabolic acidosis was reported in a 5 year-old girl who had received 2.4 mg/kg/h diazepam preserved with benzyl alcohol for 36 hours to control status epilepticus. Elevated benzoic acid concentrations were identified in serum and urine samples. The estimated daily dosage of benzyl alcohol was 180 mg/kg.^{64,97}

FIGURE 55–1. Oxidative metabolism of benzyl alcohol.

Neurologic Toxicity

Benzyl alcohol is believed to have a role in the increased frequency of cerebral intraventricular hemorrhages and mortality reported in very-low-birth weight (VLBW) infants (weight < 1000 g) who received flush solutions preserved with benzyl alcohol.⁷⁷ An increased incidence of developmental delay and cerebral palsy was also noted in the same VLBW patients, suggesting a secondary damaging effect of benzyl alcohol.¹³

There are several case reports of transient paraplegia following the intrathecal or epidural administration of chemotherapeutics or analgesics containing benzyl alcohol as a preservative.^{9,39,70,139} The local anesthetic effects are most likely responsible for the immediate paraparesis and limited duration of effects, rather than actual demyelination of nerve roots. In a rat study, lumbosacral dorsal root action potential amplitudes were measured after exposure to 0.9% or 1.5% benzyl alcohol solutions in either 0.9% sodium chloride solution or distilled water.⁷⁰ Rats exposed to all benzyl alcohol solutions for less than one minute had inhibited dorsal root action potentials. This was attributed to the local anesthetic

effects of benzyl alcohol as function was 50% to 90% restored after rinsing the nerves with 0.9% sodium chloride solution. Chronic intrathecal exposure to benzyl alcohol 0.9% over 7 days resulted in scattered areas of demyelination and early remyelination. The 1.5% benzyl alcohol solution–exposed dorsal nerve roots showed greater changes with widespread areas of demyelination and fatty degeneration of nerve fibers.

CHLOROBUTANOL

Chlorobutanol, or chlorbutol (1,1,1-trichloro-2-methyl-2-propanol), is available as volatile, white crystals with an odor of camphor. Chlorobutanol has antibacterial and antifungal properties and is widely used as a preservative in injectable, ophthalmic, otic, and cosmetic preparations at concentrations up to 0.5% (Table 55–4). Chlorobutanol also has mild sedative and local anesthetic properties and was formerly used therapeutically as a sedative-hypnotic.¹⁹ Because chlorobutanol is a halogenated hydrocarbon, theoretically it can sensitize the myocardium to catecholamines, although no cases of ventricular dysrhythmias are described in the literature to date. The lethal human chlorobutanol dose is estimated to be 50 to 500 mg/kg.¹¹⁷

TABLE 55–4. Chlorobutanol Concentrations of Common Medications and Doses

Medication	Percent	Dose (mg)
Chloramphenicol ophthalmic solution	0.5	—
Epinephrine injection	0.5	5
Epinephrine ophthalmic solution	0.5	—
Isoniazid injection	0.25	7.5
Methadone injection	0.5	10

Thiamine injection	0.5	5
Procaine injection	0.25	87
Pyridoxine HCl	0.5	5
Tobramycin ophthalmic ointment	0.5	—
Vasopressin 20 U/mL injectable	0.5	5
Vitamin A injection	0.5	5

Central Nervous System Toxicity

Chlorobutanol has a chemical structure similar to trichloroethanol (Fig. 74–1), the active metabolite of chloral hydrate, and is believed to exhibit similar pharmacologic properties. Central nervous system depression was reported in a 40 year-old alcoholic man who chronically abused Seducaps, formerly available in Australia and several other countries, a nonprescription hypnotic containing chlorobutanol as the active ingredient.¹⁹ On admission to the emergency department he had drowsiness, dysarthria, slurred speech, and occasional episodes of myoclonic movements. His peak serum chlorobutanol concentration was 100 µg/mL, decreasing to 48 µg/mL over 2 weeks, with a half-life of 3 days based on serial declining levels. This is similar to human volunteer pharmacokinetic data following oral administration of chlorobutanol demonstrating an elimination half-life of 10.3 ± 1.3 days.¹⁵⁹ His speech abnormality resolved after 4 weeks. Only chlorobutanol was detected in the patient’s urine or serum. In a second case, a possible central nervous system depressant effect from chlorobutanol was suggested in a 19 year-old woman treated with high doses of intravenous morphine preserved with chlorobutanol.⁴⁵ She received approximately 90 mg/h of chlorobutanol for several days. Her peak serum chlorobutanol concentration was 83 µg/mL, a concentration similar to that in the previous case report¹⁹; however, the

coadministration of morphine precludes the effects being attributed to chlorobutanol alone.

Ketamine is neurotoxic when administered intrathecally to animals.^{106,107} The potential neurotoxic effects of chlorobutanol as a preservative in ketamine compared with preservative-free ketamine was studied in rabbits.¹⁰⁷ Forty rabbits were given 0.3 mL intrathecally of either 1% preservative-free ketamine, 1% ketamine, 0.05% chlorobutanol, or 1% lidocaine as control. The rabbits were observed and hemodynamically monitored for 8 days and then euthanized. Histologic evaluation of the spinal cord as well as for blood brain barrier (BBB) lesions was performed. Seven of the 10 rabbits given intrathecal chlorobutanol showed both white and grey matter histologic changes as well as diffuse BBB injury. No histologic changes were seen in either ketamine groups or the lidocaine group, and only one rabbit in each ketamine group had BBB injury. These results suggest chlorobutanol should not be administered intrathecally.¹⁰⁷

A case series of five patients were given intraarterial papaverine preserved with 0.5% chlorobutanol,¹⁴⁶ which is used to prevent cerebral vasospasm in patients with subarachnoid hemorrhage. Immediately after administration of papaverine in either the left, right, or bilateral anterior cerebral arteries, patients had an acute deterioration in neurologic status. Subsequent brain magnetic resonance imaging identified selective grey matter toxicity in the territories treated with papaverine. Postmortem brain histology analysis in one patient also identified grey matter changes. The authors state the absence of white matter changes is not consistent with ischemic infarction but suggest direct toxic effect of either the papaverine or chlorobutanol. The manufacturer of the papaverine stated that no other reports had been made and the papaverine used came from two different lots; therefore, it is unclear if an unidentified independent variable caused these effects, but the authors caution using intraarterial papaverine in patients with subarachnoid hemorrhage.¹⁴⁶

Ophthalmic Toxicity

Chlorobutanol is a commonly used preservative in ophthalmic preparations and is less toxic to the eye than benzalkonium chloride.¹²¹ Chlorobutanol increases the permeability of cells by impairing cell membrane structure.¹⁵⁸ An in vitro experiment using corneal epithelial cells harvested from human cadavers demonstrated arrested mitotic activity following chlorobutanol exposure.¹⁵⁸ At the commonly formulated concentration of 0.5%, chlorobutanol may cause eye irritation, most likely due to cellular contraction of epithelial microfilaments, cessation of normal cytokinesis, cell movement, and mitotic activity.⁴⁸ Degeneration of human corneal epithelial cells specifically manifested as membranous blebs, cytoplasmic swelling, and occasional breaks in the external cell membrane has also occurred at this concentration.⁴⁸

LIPIDS

In general, there are three types of commercial intravenous lipid drug-delivery systems available: lipid emulsion, liposomal, and lipid complex (Table 55–5). Lipid emulsions are immiscible lipid droplets dispersed in an aqueous phase stabilized by an emulsifier (eg, egg, soy lecithin). Liposomes differ from emulsion lipid droplets in that they are vesicles comprised of one or more concentric phospholipid bilayers surrounding an aqueous core. Lipophilic drugs can be formulated for intravenous administration by partitioning them into the lipid phase of either an emulsion or liposome. Liposomes are capable of encapsulating hydrophilic xenobiotics within their aqueous core to exploit lipid pharmacokinetic properties.¹⁵³ Attaching a therapeutic drug to a lipid to form a lipid complex is another way to take advantage of lipid pharmacokinetics.

Table 55–5. Lipid Carrier Formulations of Common Medications

Medication	Lipid Carrier
Amphotericin B (Abelcet)	Lipid complex
Amphotericin B (AmBisome)	Liposome
Amphotericin B (Amphotec)	Cholesteryl complex
Cytarabine (DepoCyt)	Liposome
Daunorubicin (DaunoXome)	Liposome
Doxorubicin (Doxil)	Liposome (stealth)
Propofol (Diprivan)	Emulsion

Lipid carriers are biocompatible because of their similarity to endogenous cell membranes. They can be created with stable lipid membranes resistant to hydrolysis or oxidation, to decrease toxicity, and to enhance therapeutic efficacy by altering drug pharmacokinetic and pharmacodynamic parameters. The biodistribution, and the rate of release and metabolism of a drug incorporated in a lipid formulation can be regulated by the type and concentration of oil and

emulsifier used, pH, drug concentration dispersed in the medium, the size of the lipid particle, and the manufacturing process.^{123,152} Intravenous formulations are usually isotonic and have a pH of 7 to 8.¹⁵³

The rate of clearance of a lipid carrier from the blood depends on its physicochemical properties and the molecular weight of the emulsifier. Electrically charged lipid carriers are removed more rapidly than neutral particles.^{24,123} Smaller lipid particle size and high-molecular-weight emulsifiers decrease clearance. Stealth liposome formulations incorporate a polyethylene glycol coating that prevents rapid detection and clearance of liposomes by the reticuloendothelial system prolonging circulation time.¹²³ Active drug targeting can be achieved by conjugating antibodies or vectors to side chains on the emulsifier.^{24,123} For a therapeutic drug available in more than one lipid-carrier formulation (eg, amphotericin B), it is important to note that any change in the lipid formulation can alter the drug's pharmacokinetic, pharmacodynamic, and safety parameters; consequently, they are not equivalent dosage formulations ([Chap. 57](#)).

The physicochemical properties of lipid emulsions not only affect the therapeutic drugs carried by them, but the lipids themselves may also have direct pharmacologic effects on the central nervous¹⁷⁰ and immune systems.⁹³ Lipid fatty acid mediators can affect the membrane receptor channels of N-methyl-D-aspartate (NMDA) receptors, potentiating synaptic transmission.^{110,111,126,156} Dogs given a medium-chain triglyceride emulsion intravenous infusion developed dose-related central nervous system metabolic and neurologic effects, accompanied by electroencephalographic changes consistent with encephalopathy observed when serum octanoate concentration reached 0.5 to 0.9 mM.¹¹⁰ In an in vitro model, three of nine lipid emulsions tested (Abbolipid, 20% soya and safflower oil; Intralipid, 20% soya oil; and Structolipid, 20% structured triglycerides) demonstrated a dose-related activation of cortical neuronal NMDA receptor channels.¹⁷⁰ The lipid source for all but one (Omegaven, 10% fish oil) of the emulsions tested was made up solely or partially by soya oil. The authors could not explain why the other six lipid emulsions did not induce membrane currents. Adequate control for the nonlipid constituent contribution of these emulsions is lacking. In another in vitro study, the same authors found that NMDA-induced neuronal currents are reduced by an unknown factor in the aqueous portion of Abbolipid.¹⁷¹ This suggests that lipid emulsions may pharmacologically enhance the anesthetic effect of hypnotics such as propofol. The clinical relevance of these studies remains to be assessed.

Triglycerides in parenteral nutrition emulsions are implicated in altering the immune system, leading to an increased susceptibility to infection,^{56,168} and altering lung function and hemodynamics in patients with acute respiratory distress syndrome.⁹³ Phospholipid activation of phospholipase A₂ may be an initiating cause.^{56,93,168} However, it is not clear if these immunologic effects are a consequence of factors other than the lipid in the emulsion.

More recently, the sequestering properties of fat emulsions have been employed in the treatment of poisonings in both animal models and human case reports ([Antidotes in Depth: A20](#)).^{11,125,145}

PARABENS

The parabens, or parahydroxybenzoic acids, are a group of compounds widely employed as preservatives in cosmetics, food, and pharmaceuticals because of their bacteriostatic, fungistatic, and antioxidant properties ([Table 55–6](#)).¹⁴⁰ A survey conducted by the FDA identified the parabens as the second most common ingredients in cosmetic formulations, with water being the most common.⁹⁸ Parabens are often used in combination, because the presence of two or more parabens are synergistic.⁹⁸ Methylparabens and propylparabens are most commonly used.¹⁴⁰ Pharmaceutical paraben concentrations usually range from 0.1% to 0.3%.¹³⁴

TABLE 55–6. Paraben Concentrations of Common Medications and Doses

Medication ^a	Percent	Dose (mg)
Bupivacaine HCl 0.25% injection	0.1	—
Droperidol injection	0.2	2
Flumazenil injection	0.2	4
Haloperidol injection	0.2	2
Labetalol injection	0.09	4
Lidocaine injection	0.1	—
Methyldopa injection	0.17	8
Naloxone injection	0.2	2
Neostigmine injection	0.2	2
Ondansetron injection	0.14	3
Pentazocine injection	0.1	1
Pseudoephedrine/brompheniramine elixir	0.2	20
Sulfacetamide ophthalmic solution	0.06	—
Vincristine injection	0.15	4

^aAmount varies depending on volume used (contains 1 mg/mL paraben).

Widespread usage of parabens since the 1920s has shown that they have a relatively low order of toxicity.⁹⁸ However, because of their allergenic potential they are currently considered less suitable for injectable and ophthalmic preparations.¹³⁴ Based on long-term animal studies, the WHO has set the total acceptable daily intake of ethylparabens, methylparabens, and propylparabens to be 10 mg/kg body weight.¹³⁴ In addition to allergic reactions, parabens have the potential to cause other adverse effects. Bilirubin displacement from albumin binding sites occurred with administration of methyl- and propylparabens preserved gentamicin when serum parabens concentrations were 3 to 15 µg/mL.⁴¹ Gentamicin alone has no effect on bilirubin displacement.⁹² Spermicidal activity was demonstrated in an in vitro study of human semen specimens exposed to local paraben concentrations of 1 to 8 mg/mL.¹⁵⁰ Possible interference with conception and potential adverse effects on fertility were not investigated.

More recently, concern has arisen regarding the potential estrogenic and antiandrogenic effects of the parabens and their common metabolite, p-hydroxybenzoic acid. Xenobiotics with these effects are commonly referred to as endocrine disrupting substances. It has been suggested that methylparaben is less toxic than butyl and benzyl-parabens with regard to oxidative stress and resultant cytotoxicity.^{42,143} However, the clinical significance of these effects is not elucidated.^{32,43,131,132,164}

PHENOL

Phenol (carbolic acid, hydroxybenzene, phenylic acid, phenylic alcohol) is a commonly used preservative in injectable medications (Table 55–7). Phenol is a colorless to light pink, caustic liquid with a characteristic odor. When exposed to air and light, phenol turns a red or brown color.³⁸ Phenol exerts antimicrobial activity against a wide variety of microorganisms, such as Gram-negative and Gram-positive bacteria, mycobacteria, and some fungi and viruses.³⁸ Phenol is well absorbed from the gastrointestinal tract, skin, and mucous membranes, and is excreted in the urine as phenyl glucuronide and phenyl sulfate metabolites.³⁸ Although there are numerous reports of phenol toxicity following intentional ingestions or unintentional dermal exposures (Chap. 106), adverse reactions to its use as a pharmaceutical excipient are uncommon, most likely because of the small quantities used.³⁸

TABLE 55–7. Phenol Concentration of Common Medications

Medication	Percent	Dose (mg)
Antivenom (Crotaline)	0.25	25 (per vial)
Antivenom (<i>Micrurus fulvius</i>)	0.25	25 (per vial)
Dryvax (smallpox) vaccine	0.25	2.5
Pneumovax 23 (pneumococcal) vaccine	0.25	1.25
Prostigmin (neostigmine) injection	0.45	4.5
Quinidine gluconate injection	0.25	18.75
Typhoid Vi vaccine	0.25	1.25

Cutaneous Absorption

Systemic toxicity from cutaneous absorption of phenol is reported. Ventricular tachycardia was observed in an 11 year-old boy following application of a chemical peel solution containing 88% phenol in water and liquid soap. The solution was applied to 15% of his body surface area for the treatment of xeroderma pigmentosum. Immediately following the onset of the ventricular tachycardia, the phenol-treated areas were irrigated, an infusion of 0.9% sodium chloride solution was begun, and two intravenous lidocaine boluses were given followed by a lidocaine infusion. The dysrhythmia persisted for 3 hours. The urinary phenol concentration the following day was 58.9 mg/dL.¹⁶² In a similar case, multifocal premature ventricular contractions were observed in a 10 year-old boy after application of a chemical peeling solution of 40% phenol, 0.8% croton oil in hexachlorophene soap, and water for the treatment of a giant hairy nevus.¹⁶⁹ The premature ventricular contractions were refractory to intravenous lidocaine but resolved with intravenous bretylium. No phenol concentrations were obtained to confirm systemic absorption. In a case series of 181 patients undergoing chemical face peeling with phenol-based solutions, 12 demonstrated cardiac dysrhythmias. This occurred more commonly in patients with comorbid diabetes mellitus, hypertension or treatment with antidepressants. These authors recommend prophylactic administration of propranolol prior to phenol application to mitigate these dysrhythmias citing a reduction in dysrhythmia incidence in their patients.⁹¹ Despite the risk of toxicity, phenol chemical peels are still used in some cases because phenol penetrates deep into tissues providing both long-lasting and good cosmetic results. Most commonly phenol chemical peels are used for deep acne scars and other severe skin disorders.

Drowsiness, respiratory depression, and blue-colored urine were noted in a 6 month-old infant 12 hours after topical application of magenta paint over most of the body for seborrheic eczema.¹³⁶ Magenta paint (also known as Castellani paint) was widely used for seborrheic eczema and contained 4% phenol, magenta, boric acid, resorcinol, acetone, and methylated spirit. Further investigation found that phenol was detected in urine samples of four of 16 other infants with seborrheic eczema who had approximately 11% to 15% of their body surface area painted with magenta paint for 2 days.

POLYETHYLENE GLYCOL

Polyethylene glycols (PEGs; Carbowax, Macrogol) include several compounds with varying molecular weights (200–40,000 Da).¹³⁰ They are typically available as mixtures designated by a number denoting their average molecular weight. PEGs are stable, hydrophilic substances, making them useful excipients for cosmetics, and pharmaceuticals of all routes of administration (Table 55–8). Pegylation, a process that modifies the pharmacokinetics of therapeutic liposomes and proteins (eg, peginterferon- α), is the most recent application of PEG. At room temperature, PEGs with molecular weights less than 600 are clear, viscous liquids with a slight characteristic odor and bitter taste. PEGs with molecular weights heavier than 1000 are soluble solids and range in consistency from pastes and waxy flakes to powders.¹³⁰ Commercially available products used for bowel cleansing preparations and whole bowel irrigation are solutions of PEG 3350 sometimes combined with electrolytes and known as PEG electrolyte lavage solution (PEG-ELS; Antidotes in Depth: A2).

TABLE 55–8. Common Medications Containing PEG

<i>Medication</i>	<i>PEG Molecular Weight (Da)</i>
Dexamethasone ophthalmic ointment	400
Etoposide injection	300
Lorazepam injection	400
Medroxyprogesterone depot	3350
Mupirocin ointment	400, 3350
PEG electrolyte solution	3350
Peginterferon α -2a	40,000

PEG = polyethylene glycol.

The solid, high-molecular-weight PEGs are essentially nontoxic. Conversely, low-molecular-weight PEG exposures have caused adverse effects similar to the chemically related toxic alcohols ethylene and diethylene glycol²⁸ (Special Considerations: SC7).

Pharmacokinetics

High-molecular-weight PEGs (> 1000) are not significantly absorbed from the gastrointestinal tract, but low-molecular-weight PEGs may be absorbed when taken orally.^{47,147,148} Topical absorption can occur when PEGs are applied to damaged skin.^{22,154} Once in the systemic circulation, PEGs are mainly excreted unchanged in the urine⁴⁷; however, low-molecular-weight PEGs (eg, PEG 300, PEG 400) are partially metabolized by alcohol dehydrogenase to hydroxyacid and diacid metabolites. The pharmacokinetics of intravenously administered PEG 3350 has not been studied; however, it did not appear to have any systemic effects when unintentionally given by this route.¹³⁵

Nephrotoxicity

In rats fed various PEGs (200, 300, and 400) in their drinking water for 90 days, a solution of 8% PEG 200 produced renal tubular necrosis in all of the animals, followed by death within 15 days; however, a 4% PEG 200 solution resulted in only two of nine rats dying within 80 days. A 16% PEG 400 solution killed all animals within 13 days; however, both 8% and 4% PEG 400 solutions had no observable effect except for a decrease in kidney weight when compared to control animals.¹⁴⁹ A more recent study administering daily high dose PEG 400 intravenously, up to 8.45 g/kg/day, in a canine model failed to show serious renal toxicity. However, edema of kidney cells and increased glomerular volume occurred at these dosages but were reversible.⁹⁵ Acute tubular necrosis has been reported with oliguria, azotemia, and an anion gap metabolic acidosis following oral and topical exposures to low-molecular-weight PEGs (200 and 300). Acute kidney failure occurred in a 65 year-old man with a history of alcohol abuse and seizure disorder after ingestion of the contents of a lava lamp containing 13% PEG 200.⁴⁹ About 48 hours after admission (approximately 50–72 hours postingestion), the patient became oliguric with an anion gap metabolic acidosis and acute kidney failure. Blood sample analysis confirmed traces of the lava lamp fluid; no traces were detected in the urine. After clinical complications from ethanol withdrawal and aspiration pneumonitis, the patient was discharged 3 months later with residual kidney dysfunction attributed to the PEG component of the lamp contents. Acute tubular necrosis was noted on autopsy of six burn patients treated with a topical antibiotic cream in a PEG 300 base.^{22,154} Mass spectrometry detected hydroxyacid and diacid metabolites in serum and urine samples. Oxalate crystals were seen in two cases. These effects were reproduced with the topical application of PEG for 7 days to rabbits with full-thickness skin defects.¹⁵⁴

Neurotoxicity

There are reports of neurologic complications, such as paraplegia and transient bladder paralysis, following intrathecal corticosteroid injections containing 3% PEG as a vehicle.^{14,18} In an in vitro experiment, rabbit vagus nerves were exposed to concentrations of PEG 3350 ranging from 3% to 40% for one hour.¹⁴ A total of 3% and 10% PEG had no effect on nerve action potential amplitude or conduction velocity. A dose of 20% and 30% PEG significantly slowed nerve conduction and had varying effects on the amplitudes of action potentials. Forty percent PEG completely abolished action potentials. These changes were reversible and thought to be related to PEG-induced osmotic effects. More recently, the administration of PEG 1800 is being studied as a potential therapy for spinal cord injury by repairing damaged axons through cellular fusion of damaged cells following the short-term (2 minutes) application, in a guinea pig model. This increases compound action potential conduction.¹⁴⁴ Interestingly, administering a similar dose of PEG continuously for 25 minutes decreased compound action potentials approximately 64% in both damaged and non-damaged isolated mammalian spinal cords

suggesting dose-response toxicity.³⁶

Fluid, Electrolyte, and Acid–Base Disturbances

Hyperosmolality was reported in three patients with burn surface areas ranging from 20% to 56% following repeated applications of Furacin, a topical antibiotic dressing containing 63% PEG 300, 32% PEG 4000, and 5% PEG 1000.²² PEG produces an osmotic effect that is greater than expected for its molecular weight.¹⁴¹ It is theorized that PEG increases osmolality by sequestering water through hydrogen binding, which reduces the availability of water to interact with solutes, thus increasing the chemical and osmotic activity of the solute. Hyperosmolality following the administration of a PEG-containing substance may suggest systemic PEG absorption.

Two cases of metabolic acidosis were reported following administration of therapeutic dosages of an intravenous nitrofurantoin solution containing PEG 300.¹⁵⁵ Similarly, an otherwise unexplained increased anion gap was reported in three patients being treated with a topical PEG-based burn cream.²³ Metabolism of the lower-molecular-weight PEGs by alcohol dehydrogenase to hydroxyacid and diacid metabolites can explain the metabolic acidosis.⁷⁴

PROPYLENE GLYCOL

Propylene glycol (PG), or 1,2-propanediol, is a clear, colorless, odorless, sweet, viscous liquid employed in numerous pharmaceuticals (Table 55–9), foods, and cosmetics. Propylene glycol is used as a solvent and preservative with antiseptic properties similar to ethanol. The WHO has set the daily allowable intake of PG at a maximum of 25 mg/kg,¹⁷² or 1.75 g/d for a 70-kg person.

TABLE 55–9. Propylene Glycol Concentration of Common Medications

Medication	Percent	Average Dose (g) ^a
Amprenavir oral solution	55	57.75
Chlordiazepoxide injection	20	0.08
Diazepam injection	40	0.4
Digoxin injection	40	0.4
Esmolol injection	25	2.5
Etomidate	35	3.6
Lorazepam injection	80	0.64
Multivitamins injection	30	0.45
Nitroglycerin injection	30	0.3
Pentobarbital	40	1.2
Phenobarbital sodium injection	67.8	0.7
Phenytoin injection	40	4.8
Trimethoprim-sulfamethoxazole injection	40	10 ^b

^aBased on dosage for 70-kg person. ^bBased on 24-hour dosage.

Pharmacokinetics

Propylene glycol is rapidly absorbed from the gastrointestinal tract following oral administration and has a volume of distribution of approximately 0.6 L/kg.^{108,151} When applied to intact epidermis, the absorption of PG is minimal. Percutaneous absorption may occur following application to damaged skin (eg, extensive burn surface areas).

Approximately 12% to 45% of PG is excreted unchanged in the urine,⁴⁶ the remainder is hepatically metabolized sequentially by alcohol dehydrogenase to lactaldehyde, which is metabolized further by aldehyde dehydrogenase to lactic acid. Lactic acid is also formed by another metabolite, methylglyoxal.¹²⁰ Lactic acid may be oxidized to pyruvic acid and then to carbon dioxide and water.¹²⁰ The terminal half-life of propylene glycol is reported to be between 1.4 and 5.6 hours in adults and as long as 16.9 hours in neonates.^{46,153}

Cardiovascular Toxicity

Intravenous preparations of phenytoin contain 40% PG to facilitate the dissolution of phenytoin. Nine years after intravenous phenytoin became available, several deaths were attributed to the rapid administration of phenytoin used for the treatment of cardiac dysrhythmias.^{63,160,182}

Cardiovascular effects reported in these cases included hypotension, bradycardia, widening of the QRS interval, increased amplitude of T waves with occasional inversions, and transient ST elevations. Studies in cats¹⁰⁰ and calves⁶⁷ confirmed PG as the cardiotoxin. Bradycardia and depression of atrial conduction were not observed in cats pretreated with atropine, or in those with vagotomy following rapid intravenous infusion of PG, suggesting that these effects are vagally mediated.¹⁰⁰ Amplification of the QRS complex was noted in these same pretreated cats, also suggesting a direct cardiotoxic effect of PG. Similar results were reported in calves pretreated with atropine that received oxytetracycline in a PG vehicle.⁶⁷

Neurotoxicity

Smaller infants appear to have a decreased ability to clear PG when compared with older children and adults.¹⁰¹ An increased frequency of seizures was reported in low-birth-weight infants who received PG 3 g daily in a parenteral multivitamin preparation.¹⁰¹ Seizures developed in an 11 year-old boy receiving long-term oral therapy with vitamin D dissolved in PG.⁷ Serum calcium, magnesium, electrolytes, and blood glucose were normal. Seizures abated after the product was discontinued. Propylene glycol possesses inebriating properties similar to ethanol. Central nervous system depression was reported following an intentional oral ingestion of a PG-containing product.¹⁰⁸

A black-box warning was added to the product information for amprenavir (Agenerase), an oral protease inhibitor solution, because of concerns over its high PG (550 mg/mL) vehicle content.¹³⁸ The recommended daily dosage of amprenavir supplies 1650 mg/kg/day of PG. A 61 year-old man experienced visual hallucinations, disorientation, tinnitus, and vertigo after receiving a 750-mg dose (474 mg/kg PG) of amprenavir solution.⁸⁵

Ototoxicity

Otic preparations can contain up to 94% PG in solutions and 10% in suspensions as part of their vehicles.⁵² In animal studies, application of high concentrations of PG (> 10%) to the middle ear can produce hearing impairment^{113,114,166} and morphologic changes, including tympanic membrane perforation, middle ear adhesions, and cholesteatoma.^{113,154,177} Although the effects of PG in the human middle ear have not been studied, all medications applied to the external ear canal are contraindicated in patients with perforated tympanic membranes.

Fluid, Electrolyte, and Acid–Base Disturbances

Patients receiving continuous or large intermittent quantities of medications containing PG can develop high PG concentrations, particularly those with renal or hepatic insufficiency.^{27,46} Propylene glycol–induced electrolyte and metabolic disturbances are evidenced by hyperosmolality, and an elevated osmolar gap attributed to the osmotically active properties of PG. In most cases, an elevated anion gap, with an otherwise unexplained elevated lactate concentration, is also present. Metabolic acidosis and hyperlactatemia result from PG metabolism.²⁶ These adverse effects are typically reported with intravenous preparations such as lorazepam,^{5,80,179} diazepam,¹⁷³ etomidate,¹⁶³ nitroglycerin,⁴⁶ pediatric multivitamins,⁶⁵ and topical silver sulfadiazine.^{12,53,89}

Systemic absorption of PG from topical application of silver sulfadiazine cream⁵³ resulted in hyperosmolality in patients with burn surface areas greater than 35% of their body.^{12,53,89} In one study, nine of 15 burn patients had osmolar gaps (> 12) after application of the cream.⁸⁹

Hyperosmolality occurred in five infants receiving a parenteral multivitamin that provided a daily PG dose of 3 g.⁶⁵ After 12 days, one premature infant had a PG concentration of 930 mg/dL and an osmolar gap of 136. Anion gap and lactic acid concentrations were normal. In a study, 11 intubated children aged 1 to 15 months who were receiving continuous lorazepam infusions over 3 to 14 days, accumulated serum PG concentrations of 17 to 226 mg/dL did not result in significant increases in osmolar gap or serum lactate concentrations from baseline.³³ This was attributed to normal renal

function and the low cumulative PG doses received (mean, 60 g).

Several small studies have found a strong correlation between elevated PG concentrations and increased osmolar gap measurements in critically ill patients receiving intravenous lorazepam and/or diazepam.^{6,174,178,179} An osmolar gap greater than 10 has been suggested as a marker for potential PG toxicity and also indicates when to consider obtaining a serum PG concentration.¹⁷⁸ An osmolar gap of 20 corresponds to a serum PG concentration of approximately 48 mg/dL.⁶ This equation should be used cautiously, as larger, more comprehensive studies are needed to validate it. There are rare cases where PG accumulation did not result in an osmolar gap.^{66,179} In addition, elevated anion gap measurements and lactate concentrations occur. As PG toxicity can mimic sepsis in these critically ill patients, sepsis should always be considered as the potential etiology of increased lactate, hypotension, and worsening renal function when considering PG toxicity. Both hemodialysis and fomepizole have been used to treat PG toxicity.^{124,181}

Nephrotoxicity

Human proximal tubular cells exposed in vitro to PG concentrations of 500 to 2000 mg/dL exhibited significant cellular injury and membrane damage within 15 minutes of exposure.¹¹⁶ Repeated exposure for up to 6 days produced dose-dependent toxic effects at lower concentrations (76, 190, and 380 mg/dL).¹¹⁵

The chronic administration of PG may contribute to proximal tubular cell damage and subsequent decreased kidney function. In a retrospective study of eight patients who developed elevations in serum creatinine concentration while receiving continuous lorazepam infusions, serum creatinine rose within 3 to 60 days (median, 9 days).¹⁷⁹ The magnitude of serum creatinine rise was found to correlate with the serum PG concentration and duration of infusion. Serum creatinine decreased within 3 days of discontinuing the infusion. Patients with chronic kidney disease are at greater risk for accumulating PG because 45% of PG is eliminated unchanged by the kidneys⁴⁶; the remainder is metabolized by the liver. Caution should be used when prolonged administration of a PG-containing medication is necessary in the presence of renal or hepatic dysfunction.¹¹⁶

Propylene glycol induced renal tubular necrosis has been reported in several cases. Daily PG vehicle dosages of 11 to 90 g/day over 14 days was associated with rising serum creatinine concentrations (0.7–2.1 mg/dL), elevated serum lactate concentrations, osmolar and anion gaps, and a serum PG concentration of 21 mg/dL.¹⁸⁰ Urine sediment analysis revealed numerous granular, muddy-brown-colored casts and no eosinophils, suggesting an acute renal tubular necrosis. Kidney biopsy and electron microscopy showed extensive dilation of the proximal renal tubules, with swollen epithelial cells and mitochondria. Numerous vacuoles containing debris were also noted. A kidney biopsy of another case with a serum PG concentration of 30 mg/dL showed disrupted brush borders of the proximal renal tubules after a sudden rise in serum creatinine concentration (3.1 mg/dL), nonoliguric kidney failure, and metabolic acidosis. This was attributed to an average daily PG dose of 70 g for 17 days.⁷²

SORBITOL

Sorbitol (D-glucitol) is widely used in the pharmaceutical industry as a sweetener, moistener agent, and as a diluent (Table 55–10). Sorbitol occurs naturally in the ripe berries of many fruits, trees, and plants, and was first isolated in 1872 from the berries of the European mountain ash (*Sorbus aucuparia*).¹¹⁸ It is particularly useful in chewable tablets because of its pleasant taste. In addition, it is widely used by the food industry in chewing gums, dietetic candies, foods, and enteral nutrition formulations. Sorbitol is approximately 50% to 60% as sweet as sucrose.¹¹⁸

TABLE 55–10. Common Medications Containing Sorbitol

<i>Medication</i>	<i>Percent</i>	<i>Dose (g)</i>
Amantadine syrup	64	6.4
Calcium carbonate suspension	28	1.4
Carbamazepine syrup	17	0.85
Chloral hydrate syrup	40	2
Cimetidine syrup	46	2.3
Digoxin elixir	21	0.1
Ferrous sulfate infant drops	31	0.2
Furosemide solution	35	1.75
Guaifenesin/dextromethorphan syrup	64	6.4
Methadone HCl solution	14	5.6
Potassium chloride solution	17.5	1.35
Pseudoephedrine syrup	35	1.75
Sodium polystyrene in sorbitol	50	20

Pharmacokinetics

Unlike sucrose, sorbitol is not readily fermented by oral microorganisms and is poorly absorbed from the gastrointestinal tract. Any absorbed sorbitol is metabolized in the liver to fructose and glucose.¹¹⁸ Sorbitol has a caloric value of 4 kcal/g and is better tolerated by diabetics than sucrose; however, because some of it is metabolized to glucose, it is not unconditionally safe for people with diabetes and is obviously not “dietetic”.¹¹⁸

There is a concern of potentially fatal toxicity for individuals with hereditary fructose intolerance (HFI) receiving sorbitol-containing xenobiotics.⁵⁴ HFI is an autosomal recessive disorder caused by a deficiency of fructose-1,6-bisphosphonate aldolase in the liver, kidney, cortex, and small intestine.⁸⁶ This results in the accumulation of fructose-1-phosphate, which prevents glycogen breakdown and glucose synthesis causing hypoglycemia. The prevalence of HFI is most commonly reported to be one in 20,000 persons, but can range between one in 11,000 and one in 100,000.^{2,84,86}

In individuals with HFI, the prolonged administration of sorbitol, fructose, or sucrose can result in death from liver or kidney failure.^{37,142} Dietary exclusion of fructose, sucrose, and sorbitol prevents the adverse effects. This condition should not be confused with the more common disorder of dietary fructose intolerance, which is caused by a defect in the glucose-transport protein 5 system. This leads to the breakdown of fructose to carbon dioxide, hydrogen, and short-chain fatty acids by colonic bacteria, resulting in abdominal pain and bloating.⁹² Dietary fructose intolerance symptoms are minimized by limiting sorbitol, fructose, and sucrose in the diet.

Gastrointestinal Toxicity

In large dosages, sorbitol can cause abdominal cramping, bloating, flatulence, vomiting, and diarrhea. Sorbitol exerts its cathartic effects by its osmotic properties, resulting in fluid shifts within the gastrointestinal tract. Iatrogenic osmotic diarrhea is reported following administration of many different liquid medication formulations containing sorbitol.^{76,102} In a human volunteer study, 42 healthy adults ingested 10 g of a sorbitol solution. Sorbitol intolerance was detected in up to 55% of participants.⁸³ One theoretical explanation for why all participants did not experience the gastrointestinal adverse effects is unrecognized dietary fructose intolerance. Diarrhea resulting from sorbitol-containing medications is common and often overlooked as a possible etiology.^{31,73} Ingestion of large quantities of sorbitol (> 20 g/day in adults) is not recommended (Antidotes in Depth: A2).¹¹⁸

THIMEROSAL

Thimerosal (Merthiolate, Mercurothiolate), or sodium ethylmercurithiosalicylate, is an organic mercury compound that is approximately 49% elemental mercury (Hg^0) by weight.^{137,167} It is metabolized to ethylmercury and thiosalicylate. Thimerosal has a wide spectrum of antibacterial activity at concentrations ranging from 0.01 to 0.1%; however, higher concentrations are sometimes also used.^{88,112} Thimerosal has been widely used as a preservative since the 1930s in contact lens solutions, biologics, and vaccines, particularly those in multidose containers (Table 55–11). The use of thimerosal, which is necessary for the production process of some vaccines (eg, pertussis, influenza), may leave trace amounts in the final product.¹⁰ High-dose thimerosal exposure has resulted in neurotoxicity and nephrotoxicity. Although concerns exist regarding infant exposure to low-dose thimerosal through vaccinations and its effects on neurodevelopment, including possible links to causes of autism,¹⁷ these concerns are unfounded (Chap. 98).⁴⁴

TABLE 55–11. Thimerosal Concentration of Common Medications

Medication	Percent	Dose (mg)
Injectable		
Antivenom (crotaline polyvalent immune) Fab	0.003	0.03 (per vial)
Antivenom (<i>Latrodectus mactans</i>)	0.01	0.25 (per vial)
Antivenom (<i>Micrurus fulvius</i>)	0.005	0.5 (per vial)
Diphtheria and tetanus toxoids ^a	Trace	< 0.3 μg
Influenza virus vaccine ^b (various)	0.01	0.025
Menomune-A/C/Y/W-135 ^b (meningococcal vaccine)	0.01	0.025
Tetanus toxoid (adsorbed)	0.01	0.025
Topical		
Mersol (thimerosal tincture)	0.1	—
Neosporin (triple antibiotic) ophthalmic solution	0.001	—
Ocufen (flurbiprofen) ophthalmic solution	0.005	—

^aTrace defined by the US Food and Drug Administration as < 1 μg mercury each dose. ^bMultidose.

Because specific guidelines for ethylmercury exposure have not been developed, regulatory guidelines for dietary methylmercury exposure were applied to monitor ethylmercury exposure from injected thimerosal-containing vaccines. Methylmercury is a similar, but more toxic, organic mercury compound (Chap. 98). Maximum daily recommended methylmercury exposures range from 0.1 μg Hg/kg (US Environmental Protection Agency {EPA}) to 0.47 μg Hg/kg (WHO).^{3,30,35}

An FDA review of thimerosal-containing vaccines revealed that some infants, depending on the immunization schedule, vaccine formulations, and infant's weight, might be exceeding the EPA exposure limit of 0.1 μg Hg/kg/day for methylmercury. Over the first 6 months of life, a total cumulative dose of up to 187.5 μg Hg total from thimerosal-containing vaccines was possible. The US Public Health Service and the American Academy of Pediatrics jointly responded by recommending the preemptive reduction or removal of thimerosal from vaccines wherever possible.^{3,29} The WHO and European regulatory bodies have made similar recommendations.⁵⁵ To date, thimerosal has been removed from most US-licensed immunoglobulin products. All vaccines routinely recommended for children younger than 7 years of age are either thimerosal-free or contain only trace amounts (< 0.5 μg Hg/dose), with the exception of some inactivated influenza vaccines. Multidose vials requiring thimerosal preservative remain important for immunization programs in developing countries due to lack of consistent ability to refrigerate vaccines. Although efforts continue to eliminate all sources of mercury exposure, complete elimination of thimerosal from all vaccines is unlikely in the near future.¹⁰ When a thimerosal-containing vaccine is the only alternative, the benefits of vaccination far exceed any theoretical risk of mercury toxicity.¹¹⁹

Prior to thimerosal use in pharmaceuticals, evidence for its safety and effectiveness was provided in several animal species and in 22 humans.¹²⁹ Only limited data exist on infant mercury exposure from thimerosal-containing vaccines. Clinical studies that assess the effects of thimerosal exposure on neurodevelopment and renal and immunologic function are lacking. Based on a comprehensive review of epidemiologic data from the United States,^{34,58,61,157,167} Denmark,^{104,105}

Sweden,¹⁵² and the United Kingdom,^{5,75} the Institute of Medicine's Immunization Safety Review Committee,¹¹⁹ the Global Advisory Committee on Vaccine Safety,¹⁷⁶ and the European Agency for the Evaluation of Medicinal Products⁵⁰ have all concluded that no causal relationship exists between thimerosal-containing vaccines and autism. Continued surveillance of autistic spectrum disorders as thimerosal use declines will be conducted to evaluate any associated trends.

Pharmacokinetics

Limited pharmacokinetic data exist for thimerosal and ethylmercury. Once absorbed, thimerosal breaks down to form ethylmercury and thiosalicylate. Some ethylmercury further decomposes into inorganic mercury in the blood, and the remainder distributes into kidney and, to a lesser extent, brain tissue.^{104,105} Because of its longer organic chain, ethylmercury is less stable and decomposes more rapidly than methylmercury, leaving less ethylmercury available to enter kidney and brain tissue.¹⁰⁴ Ethylmercury crosses the blood–brain barrier by passive diffusion.¹⁰⁵ Intracellular ethylmercury decomposes to inorganic mercury, which accumulates in kidney and brain tissues.¹⁰⁵ The half-life of thimerosal is estimated to be about 18 days.¹⁰⁶ Thimerosal is eliminated in the feces as inorganic mercury (Chap. 98).¹²⁸

Mercury or Thimerosal Toxicity

Oral Administration. A case report described a 44 year-old man who ingested 5 g (83 mg/kg) of thimerosal in a suicide attempt; within 15 minutes he began vomiting spontaneously. Gastric lavage was performed and chelation therapy begun with dimercaptopropane sulfonate. Gastroscopy revealed a hemorrhagic gastritis. Polyuric acute kidney injury was noted on the day of admission and persisted for 40 days. Four days after admission, the patient developed fever and a maculopapular exanthem attributed to thimerosal. The patient also developed an autonomic and ascending peripheral polyneuropathy that persisted for 13 days. Chelation therapy was continued for a total of 50 days with dimercaptopropane sulfonate followed by succimer. Elevated blood and urine mercury concentration persisted for more than 140 days. The patient was discharged 148 days following the ingestion with only sensory defects in his toes. No other neurologic sequelae were noted.¹²⁷

Oral absorption of thimerosal resulted in the fatal poisoning of an 18 month-old girl from the intraotic instillation of a solution containing 0.1% thimerosal and 0.14% sodium borate. Tympanostomy tubes placed one year earlier allowed the irrigation solution to flow through the auditory tube into the nasopharynx, and subsequently to be swallowed and absorbed through the oral mucosa and gastrointestinal tract. A total of 1.2 L of solution (500 mg Hg) was instilled over a 4 week period, resulting in severe mercury poisoning. Four days after admission, the serum mercury concentration was 163 µg/dL. The patient also received 1.7 g of boric acid. It is unclear what contribution, if any, the boric acid made to the serum mercury concentration. Chelation therapy with N-acetyl-D-penicillamine was initiated on day 51. Despite increased urinary mercury concentrations following administration of the N-acetyl-D-penicillamine, her neurologic function and blood mercury concentrations remained unchanged. The child died 3 months after admission. An autopsy was not performed.¹³⁷

Intramuscular Administration. Urine mercury concentrations of 26 patients with hypogammaglobulinemia, who received weekly intramuscular immunoglobulin G (IgG) replacement therapy preserved with 0.01% thimerosal were studied. The dosages of IgG ranged from 25 to 50 mg/kg, containing 0.6 to 1.2 mg of mercury per dose.⁶⁸ The total estimated dose of mercury administered ranged from 4 to 734 mg over a period of 6 months to 17 years. Urine mercury concentrations were elevated in 19 patients, ranging from 31 to 75 µg/L; however, no patients had clinical evidence of chronic mercury toxicity.⁶⁸

Six cases of severe mercury poisoning resulting in four deaths were reported following the intramuscular administration of chloramphenicol preserved with thimerosal. A manufacturing error produced vials containing 510 mg of thimerosal (250 mg Hg) instead of 0.51 mg per vial. Two adults received 4 g and 5.5 g of mercury each and four children received 0.2 to 1.8 g each. All six patients had extensive tissue necrosis at the site of injection. Fever, altered mental status, slurred speech, and ataxia were noted. Autopsy identified widespread degeneration and necrosis of the renal tubules; however, creatine kinase concentrations were not reported, so pigment-induced nephrotoxicity cannot be excluded. Elevated mercury concentrations were found in the injection site tissues, and in the kidneys, livers, and brains.⁸

Topical Administration. Thirteen infants were exposed to nine to 48 topical applications of a 0.1% thimerosal tincture for the treatment of exomphalos. Analysis for elevated mercury concentrations was performed in 10 of 13 infants who unexpectedly died. Mercury concentrations were determined in various tissues from six of the infants. Mean tissue concentrations in fresh samples of liver, kidney, spleen, and heart ranged from 5152 to 11,330 ppb, suggesting percutaneous absorption from these repeated topical applications.⁵¹

Ophthalmic Administration. Nine patients undergoing keratoplasty were exposed to a contact lens stored in a solution containing 0.002% thimerosal.¹⁷⁵ After 4 hours, the lens was removed and mercury concentrations of the aqueous humor and excised corneal tissues were determined. Mercury concentrations were elevated in both aqueous humor (range, 20–46 ng/mL higher) and corneal tissues (range, 0.6–14 ng/mL higher) as compared with eyes that had not been fitted with contact lenses. Only residual amounts of mercury remained on the contact lenses after 4 hours of wear. The authors noted that

although the aqueous humor concentrations were in the same range as those measured in 10 patients with vision loss from systemic mercury poisoning (11–104 ng/mL), adverse effects did not occur.

A possible drug interaction between orally administered tetracyclines and thimerosal was reported to result in acute, varying degrees of eye irritation in contact lens wearers using thimerosal-containing contact lens solutions who started treatment with tetracycline.⁴⁰

SUMMARY

- The benefits of pharmaceutical excipients include improved xenobiotic solubility, stability, and palatability, antimicrobial activity, the availability of various dosage forms, the provision of products with long-term storage, and the availability of multiple-dose packaging. While excipients are essential and effective, they are suggested to possess no pharmacologic or toxicologic properties but may actually be responsible for severe—and sometimes fatal—adverse effects.
- The toxicity of pharmaceutical excipients should be considered for patients requiring high doses or prolonged administration of any medication containing excipients, particularly those additives known to have toxicities.
- Under circumstances in which there is no option but to continue treating a patient with a particular xenobiotic, switching to a preservative-free product, or to another brand without the offending excipient, may obviate the need for discontinuation of an effective xenobiotic. In addition to inherent toxicities, many excipients may also be responsible for allergic reactions.
- In the majority of cases, pharmaceutical excipients are safe and effective, and their benefits far exceed their potential for adverse effects when properly administered.

56 THYROID AND ANTITHYROID MEDICATIONS

Nicole C. Bouchard

HISTORY AND EPIDEMIOLOGY

Long before the thyroid was recognized as a functional endocrine gland, it was believed to serve a cosmetic function, especially in women. Egyptian paintings often emphasize the full and beautiful necks of women with enlarged thyroid glands. Early theories on the physiologic function of the thyroid gland included lubrication of the trachea, diversion of blood flow from the brain, and protection of women from “irritation” and “vexation” from men.³³ Although poorly defined in historical accounts, symptoms resembling hypothyroidism and myxedema that were successfully treated with ground sheep thyroid were described 500 years ago. In the 16th century, Paracelsus described the association between goiter (thyroid gland enlargement) and cretinism.⁶⁹ A syndrome of cardiac hyperactivity, goiter, and exophthalmos was first described in 1786.⁸² Graves and von Basedow³³ further detailed this syndrome and its relationship to the thyroid gland 50 years later.

In 1891, injection of ground sheep thyroid extract was formally described as a treatment for myxedema.³³ Shortly afterward, oral therapy was determined to be equally effective. Seaweed, which contains large amounts of iodine, was used to treat goiter (hypothyroidism) in Chinese medicine as early as the third century A.D. In 1863, Trousseau¹⁰¹ fortuitously discovered a treatment for Graves disease when he inadvertently prescribed daily tincture of iodine instead of tincture of digitalis to a tachycardic, thyrotoxic young woman.

Sir Charles R. Harington described the chemical structure and performed the first synthesis of thyroxine (tetraiodothyronine {T₄}) in 1926.⁸⁴ Triiodothyronine (T₃) was not isolated and synthesized until the 1950s.³³ Prior to this, desiccated thyroid gland from animal sources was commonly used to treat hypothyroidism. Despite becoming essentially obsolete in the modern medical community, unprocessed, desiccated thyroid can be easily purchased via the Internet and in health food stores as a thyroid supplement.⁹⁵ A pharmaceutical grade porcine derived thyroid supplement originally produced by Armour, is still available by prescription from several manufacturers. Unfortunately, the misguided use of both organic and synthetic thyroid supplements as vitality agents, stimulants, and weight-loss aids has become increasingly common. Two epidemics of “hamburger thyrotoxicosis” that occurred in the United States in the mid 1980s secondary to consumption of ground beef contaminated with bovine thyroid gland demonstrated the potential widespread toxicologic sequelae after a community unknowingly ingested thyroid hormone.^{38,51}

Today, hypothyroidism and hyperthyroidism are relatively common endocrine disorders. The global incidence of neonatal hypothyroidism is one per 3000 to 4500 births. It is estimated that hypothyroidism affects 1% to 5% of US adults. It is more prevalent in whites than people of Hispanic or African American descent. In the elderly, the prevalence of hypothyroidism increases to 15% by the age of 75 years. Worldwide, iodine deficiency is the leading cause of hypothyroidism. According to US retail pharmaceutical statistics for prescription drugs, levothyroxine (both generic and brand combined; T₄) has consistently ranked in the top five prescription count, with an average 67 million per year. Because of widespread availability of thyroid replacement therapy, many cases of intentional and unintentional overdoses with thyroid hormone are reported.⁶³ However, despite the profound effects of thyroid hormones on physiologic homeostasis and the widespread use and access to exogenous thyroid hormone, morbidity and mortality from overdose is very low and clinically significant overdoses with thyroid hormone preparations are uncommon.

PHARMACOLOGY

Physiology

To properly understand the impact of thyroid supplements and antithyroid xenobiotics on the function of the human body, an understanding of thyroid physiology is required. Thyroid function is influenced by the following: (1) the hypothalamus, (2) the pituitary gland, (3) the thyroid gland, and (4) the target organs for the thyroid hormones (Fig. 56–1).

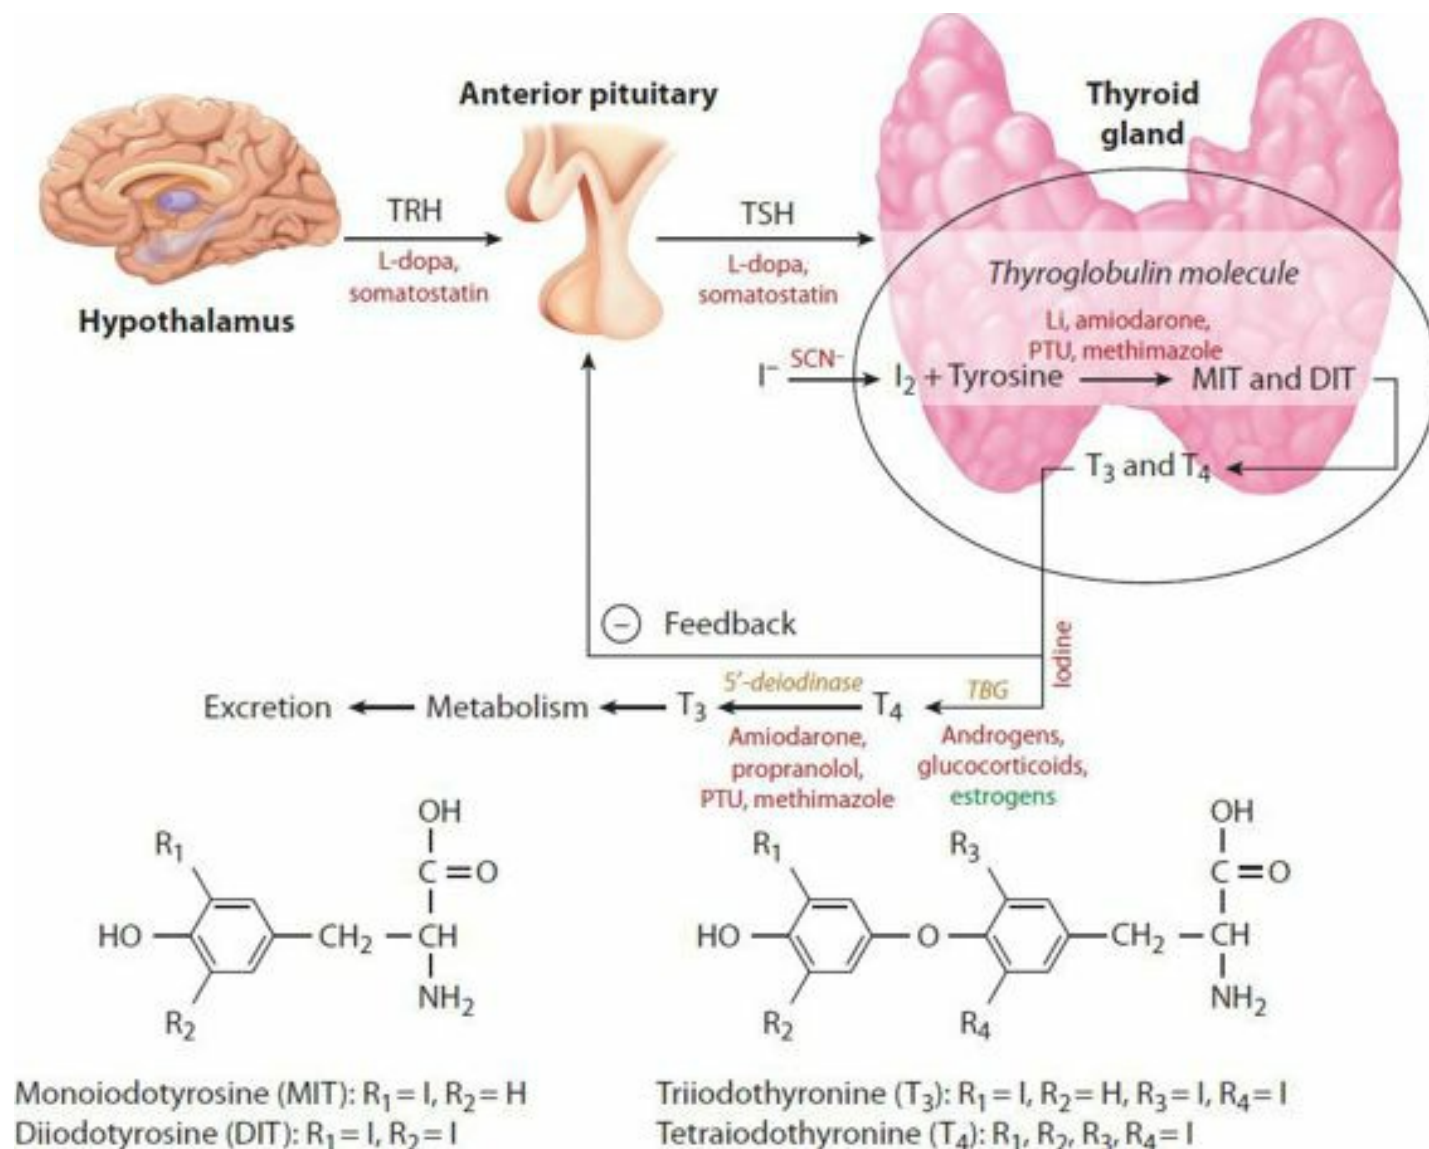

FIGURE 56–1. Thyroid hormone synthesis: its control, metabolism, and molecular structures. PTU = propylthiouracil; SCN⁻ = thiocyanate; TBG = thyroxine binding globulin; TRH = thyrotropin releasing hormone; TSH = thyroid stimulating hormone.

The hypothalamus, viewed by some as the “master gland,” is an intermediate between cerebral centers and the pituitary gland. When the hypothalamus receives specific neurotransmitter stimulation, thyroid-releasing hormone (TRH) is produced, which is then transported through the venous sinusoids to the pituitary gland, which then releases thyroid-stimulating hormone (TSH). TSH enters the circulation and stimulates the production and release of the thyroid hormones T₃ and T₄ from the thyroid gland. Thyroid physiology exhibits classic autoregulation or “negative biofeedback” of hormonal function. When adequate thyroid hormones are present, they exert an inhibitory effect on the pituitary gland, diminishing production of TSH (Fig. 56–1). Suppression or upregulation of TSH production is a frequently used laboratory marker in the evaluation of hyperthyroidism and hypothyroidism, respectively.

Thyroid hormones are tyrosine molecules with iodine substitutions. Two forms of the hormone are physiologically active: T₃ and T₄ (Table 56–1). Synthesis of thyroid hormones is a multistep process. The amino acid tyrosine is concentrated in the follicles of the thyroid gland, which consist of an epithelial layer surrounding a proteinaceous colloidal substance called thyroglobulin. Thus, thyroglobulin contains a large amount of tyrosine. After absorption, iodide (I⁻) is concentrated in thyroid cells by an active transport process called iodide trapping. Absorbed I⁻ is then oxidized to iodine (I₂) by thyroid (iodide) peroxidase. Iodine rapidly iodinates tyrosine residues to form monoiodotyrosine and diiodotyrosine. These substituted tyrosine molecules then combine to form T₃ and T₄. The ratio of T₃ to T₄ in thyroglobulin is 1:5. T₃ and T₄ (thyroxine) ultimately are released into circulation from the thyroglobulin matrix.

TABLE 56–1. Pharmacokinetic Properties of Thyroid Hormones

Pharmacokinetic Property	T_3	T_4
Oral bioavailability (exogenous drug), %	95	80
Volume of distribution (L/kg)	40	10
Half-life (days)	1	7
Protein binding (normal adult), %	99.96	99.6
Relative potency	4	1

Iodide trapping can be inhibited pharmacologically by monovalent anions such as thiocyanate (SCN^-), pertechnetate (TcO_4^-), and perchlorate (ClO_4^-). Thyroid peroxidase is inhibited by high concentrations of intrathyroidal iodide and by thioamide drugs. High intrathyroidal iodide concentrations also can inhibit the release of thyroid hormone into circulation (Table 56–2).

TABLE 56–2. Xenobiotic Interactions: Effects on Thyroid Hormones and Function^{6,26,30,100}

Xenobiotic	Interaction	Effect
Dopamine, levodopa, somatostatin	Inhibit TRH and TSH synthesis	No clinical hypothyroidism
Iodides (including amiodarone), lithium, aminoglutethimide	Inhibit thyroid hormone synthesis or release	Hypothyroidism
Monovalent anions (SCN^- , TcO_4^- , ClO_4^-)	Inhibit iodide uptake to thyroid gland	Hypothyroidism
Estrogens, tamoxifen, heroin, methadone, mitotane	Increase TBG	Altered thyroid hormone transport in serum ↑ Total measured thyroid hormone (vs free hormone)
Androgens, glucocorticoids	Decrease TBG	Altered thyroid hormone transport in serum ↓ Total measured thyroid hormone (vs free hormone)
Salicylates, mefenamic acid, furosemide	Displace T_3 or T_4 from TBG	Transient hyperthyroxinemia
Thioamides (methimazole, propylthiouracil)	Inhibit thyroid peroxidase	Decrease thyroid hormone synthesis
Phenytoin, carbamazepine, phenobarbital, rifampin, rifabutin	Induction of hepatic enzymes	↓ Total thyroid hormone measurements
Iopanoic acid, ipodate, amiodarone, propranolol, corticosteroids, propylthiouracil	Inhibition of 5'-deiodinase	Decrease peripheral conversion of T_4 (↓ T_3 , ↑ rT_3)
Cholestyramine, colestipol, aluminum hydroxide, sucralfate, ferrous sulfate, some calcium preparations, infant soy formula	Interfere with GI absorption of T_4	Decreased oral bioavailability of T_4
Interleukin- α , interleukin-2	Induction of autoimmune thyroid disease	Hyperthyroidism or hypothyroidism

GI = gastrointestinal; TBG = thyroid-binding globulin; TRH = thyroid-releasing hormone; TSH = thyroid-stimulating hormone.

Approximately 95% of circulating or peripheral thyroid hormone is T_4 ; the remainder is T_3 . Only 15% of the peripheral T_3 is secreted directly by the thyroid; the balance results from the peripheral (meaning outside the thyroid gland) conversion of T_4 to T_3 . When circulating T_4 enters the cell, it is deiodinated to T_3 . Deiodination of the T_4 molecule occurs by monodeiodination of either the outer ring or the inner ring by 5'-deiodinase or 5-deiodinase, yielding 3,5,3'- T_3 and 3,3',5'-triiodothyronine (reverse T_3 { rT_3 }), respectively.⁵⁶ T_3 has approximately four times greater hormonal activity than T_4 , whereas rT_3 is metabolically inactive. T_3 exerts its effects by binding to thyroid hormone receptors inside the nucleus. This interaction with nuclear receptors regulates gene transcription and protein synthesis, which ultimately increases oxygen consumption and underlies the thermogenic effects of thyroid hormones.

Propranolol, corticosteroids, ipodate (iodinated oral contrast agent), starvation, and severe illness inhibit 5'-deiodinase, which results in decreased production of metabolically active T_3 and preferential monodeiodination to metabolically inactive rT_3 leading to a syndrome known as “sick euthyroid” (Table 56–2). This energy conserving effect allows attenuation of the thermogenic effects of thyroid hormones in times of physiologic stress.⁹⁹

T_4 and T_3

Thyroid supplementation for treatment of hypothyroidism is in widespread use both in human and veterinary medicine. Thyroid hormones historically were derived from animal origin, but now are largely synthetically produced. Desiccated and processed porcine thyroid contains both T₃ and T₄. Because it is less pharmacologically stable and carries a risk of allergic reaction and thyrotoxicity from T₃, its use has largely been supplanted by the safer synthetic alternatives.

Levothyroxine is the preparation of choice because of its low immunogenicity, 7-day half-life, and easy dosing regimen. It is also available in an intravenous (IV) formulation. Synthroid is the commercial name of the most commonly prescribed form of T₄. Liothyronine (T₃ preparation, Cytomel or Triostat, available in oral {PO} and IV) and liotrix (combination T₃/T₄ preparations, preparations of Thyrolar, available PO) are synthetic preparations that are seldom used clinically because of their short half-lives, high cost, unique therapeutic indication, and increased risk of thyrotoxicosis.

Steady state with regard to suppression of TSH and elevation of T₄ is reached approximately 6 to 8 weeks after initiation of therapy. Doses usually are titrated in increments of 12.5 or 25 µg/day after 2 to 6 weeks based on TSH measurements. [Table 56–3](#) gives typical levothyroxine doses. Different sources suggest that the bioequivalence of Synthroid may or may not be equivalent to generic levothyroxine.¹⁷ As a result, thyroid hormone concentrations and the patient’s clinical status should be followed when transitioning between levothyroxine formulations because the switch may present a risk for an adverse drug event.

TABLE 56–3. Typical Levothyroxine Doses^a

<i>Age Group</i>	<i>Dose (µg/kg/day)</i>	<i>Usual Daily Dose^b (µg/day)</i>
Infants <6 months	8–10	25–50
Infants 6–12 months	6–8	50–75
Children 1–5 years	5–6	75–100
Children 6–12 years	4–5	100–150
Children >12 years	2–3	Until 150 (adult dose)
Adults	1.7	100–150
Elderly	Enhanced sensitivity to thyroxine excess	12.5–50

^aAll levothyroxine dosing is titrated by laboratory assessment. ^bThis dose is a fixed dose estimate (alternative).

PHARMACOKINETICS AND TOXICOKINETICS

Gastrointestinal absorption of exogenous thyroid hormone occurs primarily in the duodenum and ileum. Gastrointestinal absorption can be decreased by variations in intestinal flora and binding by xenobiotics ([Table 56–2](#)). In circulation, T₃ and T₄ both are highly but reversibly bound to plasma proteins—approximately 99.6% and 99.96%, respectively (in nonpregnant adults). Thyroxine-binding globulin binds approximately two-thirds of the circulating thyroid hormones; albumin and other proteins bind the remainder. It is estimated that only 0.4% of T₃ and 0.04% of T₄ exist in the free form. Exogenously derived thyroid hormones exhibit similar binding characteristics when dosed in a physiologic range. The amount of thyroid hormone bound to proteins varies greatly with different physiologic and pharmacologic conditions, for example, increasing in pregnancy and levothyroxine overdose and decreasing in chronic disease.⁴⁰ These changes in protein binding must be considered when measuring total thyroid hormone concentrations in the blood (see Diagnostic Testing). [Table 56–1](#) lists some important pharmacokinetic properties of thyroid hormones.

Thyroid hormones undergo their ultimate metabolism peripherally. Intracellular sequential deiodination accounts for approximately two-thirds of inactivation. Most of the remaining third undergoes hepatic metabolism by glucuronidation or sulfation. Xenobiotics that induce hepatic microsomal metabolism, such as rifampin, phenobarbital, phenytoin, and carbamazepine, increase the metabolic clearance of T₃ and T₄ ([Table 56–2](#)).

PATHOPHYSIOLOGY

Thyroid hormones are critical for optimal physiologic growth and function. Thyroid function is the most important determinant of basal metabolic rate. In addition, the thyroid exerts a permissive effect on many hormones, notably catecholamines and insulin.

Hyperthyroidism is a condition characterized by excess active thyroid hormone. Most aspects of carbohydrate, protein, and lipid metabolism are increased in the presence of thyroid hormone excess. The disorder is characterized by manifestations of increased metabolism such as hyperthermia, weight loss, diarrhea, heat intolerance, and diaphoresis, along with tachycardia, widened pulse pressure, tremor, anxiety, other behavioral changes, and sometimes tachydysrhythmias such as rapid atrial fibrillation, extrasystoles, and high output congestive heart failure.^{23,53,92} This constellation of symptoms, called thyrotoxicosis, may result from overproduction of the hormone, increased conversion from T₄ to T₃, or intake of exogenous hormone. Graves disease (diffuse toxic goiter), an autoimmune disorder, is the most common cause of excess thyroid hormone secretion. It accounts for approximately two-thirds of cases and often is accompanied by exophthalmos and diffusely enlarged, nontender thyroid gland. Toxic multinodular goiter, toxic thyroid adenoma, iodine or amiodarone exposure (which can also cause hypothyroidism; [Table 56–4](#)), thyrotoxicosis factitia, and thyroiditis (eg, postpartum, Hashimoto, DeQuervain) are some other etiologies of hyperthyroidism.³¹ Severe thyrotoxicosis with significant rapid clinical decompensation is referred to as thyroid storm or thyrotoxic crisis. Thyroid storm typically occurs when untreated or undertreated hyperthyroidism occurs simultaneously with a physiologic stressor such as trauma, infection, diabetic ketoacidosis, or surgery. In early stages, patients are hyperthermic and markedly tachycardic, tremulous, agitated, or psychotic with nausea, vomiting, and diarrhea. As the disease progresses, stupor, coma, and hypotension may ensue. General treatment strategies include early airway control, crystalloid fluid resuscitation, β -adrenergic antagonist administration, parenteral corticosteroids if adrenal insufficiency is suspected, and antithyroid medications such as propylthiouracil and methimazole. β -Adrenergic antagonists such as propranolol are the mainstay of treatment, with propranolol the preferred choice because it decreases peripheral conversion of T₄ to T₃. Mortality in thyroid storm, even with treatment, can approach 20%.^{23,90}

TABLE 56–4. Common Xenobiotics That Alter Thyroid Function and Cause Clinically Important Effects^{11,26,35,36,55,100,107}

<i>Xenobiotic</i>	<i>Effect</i>	<i>Mechanism</i>
Lithium	Goiter (in 37% of patients) Hypothyroidism (in 5%–15% of patients)	Mechanism unclear
Amiodarone (37% iodine by weight)	1. Hypothyroidism (in 25% of patients) 2. Hyperthyroidism, type 1: in patients with preexisting goiters from low iodine intake 3. Hyperthyroidism, type 2: in patients with previously normal thyroid function	1. Inhibition of 5'-deiodinase 2. Type 1: iodine excess stimulates thyroid hormone production 3. Type 2: causes thyroid inflammation
Propranolol	↓ Peripheral conversion of T_4 to T_3	Inhibition of 5'-deiodinase
PTU (propylthiouracil) or methimazole	Decreased thyroid hormone synthesis ↓ Peripheral conversion of T_4 to T_3	Inhibition of thyroid peroxidase Inhibition of 5'-deiodinase
Corticosteroids	↓ Peripheral conversion of T_4 to T_3	Inhibition of 5'-deiodinase
Iodine	1. Low dose: transient or no effect 2. High doses (>10 mg/day): ↓ thyroid hormone secretion 3. Transient thyrotoxicosis (ie, Jod-Basedow effect) With rapid correction of hypothyroidism from iodine deficiency from topical iodine 4. Delirium 5. Caustic injury	1. Transiently stimulates thyroid hormone secretion 2. Inhibition of thyroid hormone synthesis 3. Increases thyroid hormone synthesis 4. Mechanism unclear 5. Direct cytotoxic injury to cells
Iodinated contrast material	1. Rapid ↓ peripheral conversion of T_4 to T_3 (adjunctive treatment in thyroid storm) 2. Prolonged suppression of T_4 to T_3 3. Causes thyrotoxicosis and thyroid storm 4. Iodide "mumps"	1. Inhibition of 5'-deiodinase 2. Mechanism unclear 3. Mechanism unclear 4. Idiopathic, toxic accumulation of iodide
Radioactive iodine	Treatment of hyperthyroidism, causes hypothyroidism	Uptake into thyroid follicles causes local destruction
Anion inhibitors ^a	↓ Iodine uptake into thyroid follicle, used in iodide-induced hyperthyroidism	Blocks uptake of iodide into the thyroid gland by competitive inhibition

^aAlso referred to as monovalent anions, ie, thiocyanate (SCN^-), perchlorate (ClO_4^-), and periodate (IO_4^-).

Since plasma catecholamine concentrations are normal or decreased in hyperthyroid states, an increase in sensitivity to catecholamines is thought to be responsible for the increased inotropy and chronotropy produced by thyroid hormones.^{14,88} Several general mechanisms are proposed for the direct cardiac effects of thyroid hormones, although their relative contributions are uncertain^{3,16,52,103}:

- T_3 increases the number of β -adrenergic receptors in various tissues, including cardiac cells.¹⁶ This process occurs via upregulation of β -adrenergic receptor synthesis at the level of the β -adrenergic gene.⁴
- T_3 modulates myocyte intracellular signaling mechanisms that lead to increased catecholamine effects. Enhancement of intracellular signaling activity involving protein kinase A, cyclic adenosine monophosphate, G proteins, and increased phosphorylation of thyroid hormone receptor proteins all are implicated to varying degrees.^{22,53,86,87,91,98,104}
- Enhancement of myocardial transmembrane and sarcoplasmic reticulum ion channel function, L-type voltage-gated Ca^{2+} channels, and accelerated Ca^{2+} entry into the sarcoplasmic reticulum also are suggested.^{49,50,74,97} Whether the effects on intracellular signaling represent a direct effect of T_3 on intracellular signaling mediators or T_3 induced augmentation of the individual β -adrenergic receptor response to catecholamines with a secondary change in postreceptor signaling is unclear.³

In addition to these mechanisms, T_3 upregulates synthesis of cardiac thyroid hormone receptors (at TR- α and TR- β genes), and the thermogenic effects of thyroid hormones can cause decreased systemic vascular resistance leading to a reflex (and indirect) increase in cardiac output. Comprehensive reviews on this topic explore the more complex cellular aspects of thyroid hormones and their effects on the cardiovascular system.^{15,53,80}

Hypothyroidism, a condition characterized by decreased basal metabolic rate and decreased catecholamine effects, is a common disorder, especially in women and the elderly. Worldwide, dietary iodine deficiency remains the leading cause of

hypothyroidism. In certain parts of the world, particularly mountainous regions such as the Andes, Alps, and Himalayas, goitrous hypothyroidism remains endemic. Untreated congenital thyroid deficiency and severe dietary iodine deficiency (goitrous hypothyroidism) in young children result in profound, irreversible mental retardation and dwarfism (also referred to as cretinism). In developed nations, the iodization of table salt has essentially eliminated dietary iodine deficiency as a cause of hypothyroidism leaving autoimmune etiologies as the most common cause, although thyroid function diminishes significantly with age in many patients. Treatment of Graves disease with radioactive iodine typically results in hypothyroidism within one year. Thyroiditis (eg, postpartum, Hashimoto, DeQuervain) may cause hypothyroidism (or hyperthyroidism) as may exposure to certain xenobiotics such as amiodarone and lithium (Table 56–4). Myxedema and myxedema coma are potentially life-threatening emergencies that represent extremes of hypothyroidism. Hypothyroidism is not discussed in more detail in this chapter, except to note that treatment of hypothyroid emergencies, especially with T₃, can result in thyrotoxic signs and symptoms. Comprehensive reviews of hypothyroidism are available.⁹⁴

CLINICAL MANIFESTATION

Symptoms of toxicity from exogenous thyroid hormone resemble those of catecholamine excess. Pronounced catecholaminelike effects occur in the cardiovascular system, especially tachycardia, tachydysrhythmias (usually atrial fibrillation or flutter), thromboembolism (from both atrial fibrillation and endothelial activation), and cardiac failure.^{23,53,92} Interestingly, although hyperthyroid patients typically are anxious, restless, or agitated, patients with thyroid storm may present with a decreased level of consciousness or even coma.^{8,43,57,89,96} Hyperthermia can occur secondary to the thermogenic effects of thyroid hormones and psychomotor agitation. Hyperthermia can be extreme (ie, > 106°F {> 41°C}). The tachycardia associated with thyrotoxicosis often is disproportionately elevated when compared to the temperature elevation.

Acute Toxicity

Acute overdoses with thyroid hormone preparations most commonly occur with oral levothyroxine. Significant ingestions of levothyroxine do not typically manifest clinically until 7 to 10 days after exposure, but rarely can occur as early as 2 to 3 days postingestion.^{32,66,90} The delay of peripheral conversion of T₄ to the metabolically active T₃ and the time required to activate nuclear receptors and protein synthesis account for this clinical latency. By contrast, acute overdoses involving preparations containing T₃ may be clinically manifest within the first 12 to 24 hours after exposure.⁶²

In children, acute thyroxine overdoses almost universally are benign because the ingestions are typically unintentional and of a low dose. Most children remain asymptomatic or develop only mild symptoms. No deaths have been reported.^{20,27,45,58,63,66,100} In a series of 15 pediatric patients with unintentional ingestion, only 3 children developed mild symptoms; these mild signs and symptoms developed within 12 to 48 hours of the exposures and resolved within 24 to 60 hours.⁶⁰ Similarly, a case series that involved 41 children (ages 1–5 years) with unintentional exposures to thyroxine (estimated doses ranged from 40 to 800 µg) found mild signs and symptoms (hyperactive behavior, tachycardia, fever, vomiting, diarrhea, diaphoresis, and flushing) in only 27%. All children had good clinical outcomes. The degree of symptoms did not correlate with the amount ingested or measured serum thyroxine concentrations (measured 1–5 hours postingestion) for most cases in that series (see Diagnostic Testing).²⁷ Two other series involving 78 and 92 cases of unintentional exposures in children found that mild symptoms developed in only four and eight patients, respectively.^{66,105} A report involving an intentional exposure of 9900 µg in a 13 year-old boy treated empirically with activated charcoal, dexamethasone, and oral propranolol described only mild tremors and anxiety.⁶⁵ A 2.5 year-old boy exposed to an estimated 7600 µg and was treated with activated charcoal approximately one hour after exposure and released home. He returned approximately 24 hours with mild tachycardia and hyperthermia and decrease in appetite. No other treatments were administered. Over the next month he experienced desquamation of the palms and soles and irritability.⁴² Only three cases of severe toxicity in children are reported: one child without a history of a seizure disorder had two seizures 7 days after a levothyroxine ingestion (18,000 µg),⁵⁶ another 2.5 year-old developed thyroid storm with lethargy on postingestion day 5 (estimated ingestion was 6000 µg, no activated charcoal was administered, and he was treated with oral propranolol)⁵⁸ and another child became gravely ill for a 12-hour period (blood pressure, 120/68 mm Hg; pulse, 200 beats/minute; temperature 104°F {40°C}) 6 hours after ingesting a large amount (3.2 g, or 50 grains) of a desiccated thyroid preparation containing both T₃ and T₄.⁶¹ All of these children made a full recovery.

Exposures in adults have a wide range of toxicity. Many patients are asymptomatic or mildly symptomatic.^{29,64,77} Severe sequelae occur more frequently in adults than in children. Symptoms resemble thyrotoxicosis and, in extreme cases, thyroid storm. Hyperthermia,^{32,58,96} dysrhythmias,^{5,58,96} and severe agitation³³ are well described. Hemiparesis,⁸ muscle weakness,^{8,96} coma,^{8,58,96} respiratory failure,²⁵ sudden death,⁷ myocardial infarction,⁷ cardiac failure,⁸ focal myocarditis,⁷ rhabdomyolysis with muscle necrosis,⁸ delayed palmar desquamation (> 2 weeks postingestion),^{8,96} and hematuria³² are also described. Because patients are expected to be asymptomatic shortly after ingestion and laboratory tests correlate

poorly with the degree of symptoms, clinical and laboratory findings early in the course of the ingestion are not reliable indicators of which patients will become ill (see Diagnostic Testing).

Chronic Toxicity

Following chronic excessive thyroid hormone ingestion, patients may present with thyrotoxicosis or have a more subtle and insidious presentation. Classically, chronic ingestion of excess thyroid hormone occurs in patients with hypothyroidism, psychiatric disorders, and eating disorders. Persons who ingest thyroid hormones chronically may develop significant weight loss, anxiety, and accelerated osteoporosis.⁷⁶ More severe manifestations, such as cardiac dysrhythmias, tachycardia, cardiac failure, and psychosis, also occur. As in patients with hyperthyroidism, intercurrent illness and physiologic stressors can trigger thyroid storm in these patients.

Numerous miniepidemics of hyperthyroidism and thyrotoxicosis have resulted from the consumption of ground meat containing neck muscle contaminated with thyroid gland.^{18,38,51} Investigators in one of these epidemics had three volunteers consume a single large portion of “well-cooked” epidemic implicated ground beef that previously had been frozen. Although all volunteers remained asymptomatic, the mean serum peak T₄ (8–12 hours postingestion) was elevated approximately 15 µg/dL, and TSH remained undetectable for 4 to 17 days.³⁸ The practice of gullet trimming (using larynx muscles for beef) that led to these outbreaks has since been prohibited in US slaughter houses. However, the risk for sporadic cases remains, especially when laryngeal muscles are used or when farmers and hunters butcher their own meat.⁸¹ Until an exogenous source of thyroid hormone is suspected or identified, such patients often are misdiagnosed with painless thyroiditis or thyrotoxicosis factitia.

Thyrotoxicosis factitia is a symptomatic disorder that mimics physiologic disease. It occurs with intentional chronic ingestion of exogenous thyroid hormone. The pattern of ingestion typically is surreptitious and maladaptive. Patients frequently have comorbid psychiatric disorders, such as Munchausen syndrome or eating disorders, or are taking thyroid hormone for secondary gain.³⁴ Patients with thyrotoxicosis factitia tend to be either health care professionals with access to medications or prescriptions or persons with access to thyroid medications being taken by relatives, friends, or pets.^{28,34,70}

In recent years, thyroid hormones have gained popularity among dieters and athletes who use the hormones as weight loss aids and as stimulants. Severe consequences can occur. Sudden death was reported in three patients suspected of chronic ingestion of thyroid hormone for weight loss and energy enhancement (for which there is a black box warning).⁷ In 2002, the heavily promoted Singaporean diet pill (Slim 10) was linked to hepatotoxicity and hyperthyroidism in numerous patients.³⁸ Investigators found the proprietary herbal preparation was adulterated with significant amounts of the undeclared ingredients T₄, T₃ (from thyroid gland extract), and fenfluramine (a drug banned by the US Food and Drug Administration). The medication was promptly withdrawn and the manufacturers convicted under the Singapore Poisons Act.³⁷ Similar cases were reported from Hong Kong, Japan, and France following ingestion of “slimming pills” containing animal thyroid extract.^{48,78,85} Unfortunately, thyroid hormone-containing supplements are promoted and are readily available to the general public without a prescription through the Internet and in stores selling nutritional supplements (Chap. 45).⁹⁵

DIAGNOSTIC TESTING

Traditionally, thyroid testing involved combinations of measurement of total T₄ and some measurement of hormone binding (T₃ uptake). Free T₄ and T₃ also can be measured by equilibrium dialysis (free T₄), analogue assays (ie, competitive analogs of either free T₃ or free T₄ that competitively bind for spaces on the serum-binding proteins), and antibody capture assays (ie, sequential assays that capture a representative portion of the free fraction of thyroid hormone). Assessment of pituitary production of TSH has improved greatly in recent years. Since supersensitive TSH assays can readily detect suppression of TSH production, TSH is now the primary test for screening thyroid function. Suppressed or elevated concentrations of TSH can be reflexively followed up with a free T₄ assay and, if necessary, a free T₃ assay (Table 56–5).

TABLE 56–5. Diagnostic Tests for Thyroid Hormone and Thyroid Function

<i>Diagnostic Test</i>	<i>Normal Values^a</i>	<i>Comments</i>
TSH	0.5–4.7 IU/mL	Available assays with respective detection limits: First-generation 1.0 IU/L Second-generation 0.1 IU/L Third-generation 0.01 IU/L
Total T ₄ by RIA	4.5–12.5 µg/dL (58–161 nmol/L)	↑ In pregnancy, estrogens, oral contraceptives
Total T ₃ by RIA	80–200 ng/dL (0.9–2.8 nmol/L)	↑ In pregnancy, estrogens, oral contraceptives
Free T ₄	8–18 pg/mL (10–23 pmol/L)	↑ In hyperthyroidism, exogenous thyroxine ingestion
Free T ₃	2.3–4.2 pg/mL (3.5–6.5 pmol/L)	↑ In hyperthyroidism, exogenous thyroid hormone (T ₃ or T ₄)

^aInterlaboratory and interassay variations may occur.

RIA = radioimmunoassay; TSH = thyroid-stimulating hormone.

The clinical manifestations of thyrotoxicosis and thyroid storm are well known to occur at normal, low, moderate, and high concentrations of T₃ and T₄.¹⁰ This lack of correlation between symptoms and serum concentrations is also true for exogenous thyroid hormone ingestion.^{8,27,32,38,56,62,66,77,105} In a large case series of children with unintentional exposures of thyroxine estimated to be between 40 and 800 µg, serum T₄ concentrations were drawn in 11 (1–5 hours postingestion). Serum T₄ concentrations were normal in five of these children and were slightly elevated in six (mean, 16 µg/dL). In this series, one infant who was estimated to have ingested 4500 µg had a significantly higher concentration (55 µg/dL at 4.5 hours) but developed only a transient episode of diaphoresis and a “staring spell” 7 days postingestion. Another child who ingested an estimated 4200 µg had a concentration of 12 µg/dL and developed significant tachycardia and hyperthermia.²⁸ A young child (estimated ingestion 18,000 µg levothyroxine) had a serum T₄ concentration of 117 µg/dL 8 hours postingestion and 38 µg/dL on day 7, when he was symptomatic.⁵⁶ Similar trends were observed for both T₃ and T₄ in three other massive levothyroxine ingestions in children.^{4,65,68} In an adult with a massive ingestion of levothyroxine (720,000 µg), serum T₄ concentrations were higher than 30 µg/dL and free T₄ was above 13 ng/dL (normal range, 0.7–1.86 ng/dL). In this case, TSH remained undetectable until postingestion day 32.³² Overall, the observed symptoms following thyroid hormone ingestion correlate poorly with the amount ingested or with measured serum T₄ concentrations. Prolonged suppression of TSH is common following ingestion of excess thyroid hormone.

Routine analysis of laboratory thyroid function tests in the setting of acute thyroid hormone overdose likely will not affect management. Analysis of thyroid hormone concentrations is indicated only if confirmation of a suspected ingestion is desired and in massive ingestions when early and severe symptoms may occur. Suppression of TSH and elevated thyroid hormone concentrations with a low serum thyroglobulin concentration may help to differentiate between thyrotoxicosis factitia and true endogenous disease.⁷⁰

MANAGEMENT

Based on the existing literature, conservative management is adequate in most cases of acute unintentional thyroxine ingestions in both adults and children. Most children with acute overdose are managed with home observation and follow-up appointments. In cases where the acute thyroxine dose is estimated to be greater than 4000 µg, patient follow-up by regular telephone contact for 10 days is suggested.²⁷ Historically, most children with unintentional ingestions have been treated with GI decontamination with activated charcoal and/or syrup of ipecac, or by gastric lavage,^{27,45,56,58,66,63} but these procedures (especially emesis and lavage) are probably unnecessary. Based on two large series of unintentional exposures in children in which no toxicity was observed in the vast majority of cases, clinically significant toxicity is not expected with estimated ingestions less than 4000 µg.^{27,107} Because children almost uniformly develop no more than minor symptoms, activated charcoal administration should be considered only if the ingestion is greater than 5000 µg of thyroxine. Aspiration risks are minimal in awake, alert children who are able to protect their airways and take activated charcoal

orally, without nasogastric tube placement.^{58,105} By extension, adults with acute ingestions greater than 5000 µg of thyroxine also should be treated with activated charcoal. Except in early presentations with massive thyroxine ingestions (>10,000–50,000 µg) in suicidal adults or ingestions of preparations containing large amounts of T₃, gastric emptying procedures such as orogastric lavage are unwarranted.^{8,32} Similarly, patients with massive ingestions (>10,000–50,000 µg) or ingestion of T₃-containing products should be admitted for observation in anticipation of developing significant symptoms.^{8,32,56,61}

Treatment should be based on the development of toxicity and should include rehydration, airway protection, and control of sympathomimetic symptoms, mental status alterations, and hyperpyrexia. β-Adrenergic antagonism with propranolol has been used for sympathomimetic symptoms in numerous cases.^{24,45,56,66,77,100} Empiric treatment with β-adrenergic antagonists is not recommended. Treatment is only indicated for clinically significant tachycardia, dysrhythmias, and other signs and symptoms of catecholaminelike excess.²⁴

Agitation

If sedation is required, parenteral benzodiazepines and barbiturates are recommended. Rapid-acting benzodiazepines, such as midazolam, or diazepam should be used to control severely agitated or symptomatic patients. Phenobarbital should be considered as an additional treatment in intubated patients or as an adjunct in patients requiring sedation because it offers the added theoretical benefit of inducing enhanced hepatic elimination of thyroxine (Table 56–2). Because of the general risks of sedation and the lack of evidence regarding the clinical use of enhanced hepatic elimination from phenobarbital, sedation with phenobarbital for the sole purpose of enhanced elimination is not indicated. Sedation with antipsychotics such as haloperidol and droperidol should be avoided because their significant anticholinergic properties can exacerbate thyrotoxic symptoms. In addition, the tendency for this class of drugs to prolong the QT interval and predispose to malignant dysrhythmias is of concern in the already catecholaminergic patient. Antipsychotics should be reserved for medically stable patients with psychiatric behavioral disturbances.

Catecholaminelike Excess and Cardiovascular Symptoms

The principal therapeutic role of β-adrenergic antagonists in hyperthyroidism is for their sympatholytic effects.⁷⁶ In addition, propranolol inhibits 5'-deiodinase, thereby decreasing peripheral conversion of T₄ to T₃ (Table 56–2). The clinical significance of decreased peripheral conversion in the setting of overdose is unknown. Propranolol is the most frequently used β-adrenergic antagonist in thyrotoxic patients,^{27,45,56,66,77,100} and should be used parenterally when signs and symptoms are severe or when rapid control of heart rate is required. Starting doses of 1 to 2 mg IV propranolol every 10 to 15 minutes are recommended. Higher doses have been reported in massive thyroxine overdose, where a patient received 23 mg propranolol IV over one hour on initial presentation, then required an average of 30 mg/day IV for 5 more days.³² Oral propranolol can be used for persistent symptoms in patients who are both hemodynamically and medically stable and are not acutely agitated. High oral doses in the range of 20 to 120 mg every 6 hours may be required. Other β-adrenergic antagonists, such as atenolol, nadolol, metoprolol, and esmolol, can be used for symptoms of adrenergic excess, but these may not inhibit the peripheral conversion of T₄ to T₃. Continuous electrocardiographic and hemodynamic monitoring are indicated when parenteral β-adrenergic antagonists are used or when patients require hospitalization.

When nonspecific β-adrenergic antagonists are contraindicated, as in patients with asthma or severe congestive heart failure, β₁-selective antagonists (such as atenolol or metoprolol) or calcium channel blockers can be used as an alternative. Among calcium channel blockers, diltiazem is the most studied for the management of thyrotoxicosis.^{68,88} A double-blind, crossover trial that compared propranolol to diltiazem for thyrotoxic symptoms found that diltiazem was well tolerated and appeared as effective as propranolol.⁷³ Another study successfully used diltiazem as the sole treatment of cardiovascular signs and symptoms in 11 thyrotoxic patients.⁹³ Oral doses of 60 to 120 mg diltiazem three to four times daily or 5 to 10 mg/h parenterally have been used.^{73,93} A possible explanation for the efficacy of calcium channel blockers in thyrotoxicosis is that thyroid hormone enhances Ca²⁺ uptake by L-type voltage-gated Ca²⁺ channels, accelerates Ca²⁺ entry into the sarcoplasmic reticulum, and increases cellular Ca²⁺ storage capacity.^{49,50,74,97} The net effect of these changes is increased inotropy and chronotropy. Calcium channel blockers, particularly diltiazem and verapamil, attenuate these effects. However, the use of parenteral β-adrenergic antagonists in combination with parenteral calcium channel blockers is contraindicated because of the risk for profound hypotension and cardiovascular collapse.⁷⁹

Hyperthermia

Antipyretics are not recommended for hyperthermia associated with catecholamine excess and thyrotoxic condition. Aspirin, particularly high doses (1.5–3 g/day), should be avoided because it carries a theoretical risk of increased thyrotoxicity from displacement of T₃ and T₄ from thyroxine-binding globulin (Table 56–2). Note, however, that hyperthermia, especially extreme hyperthermia (> 106°F {> 41°C}), is most likely secondary to psychomotor agitation and excess heat production from the hypermetabolic, catecholaminergic, and thyrotoxic conditions. Extreme hyperthermia

should be considered a medical emergency and should be rapidly and aggressively treated with active external cooling with ice baths and with β -adrenergic antagonism, sedation with benzodiazepines and/or barbiturates, and endotracheal intubation with paralysis if necessary (Chap. 30).

Other Therapies

Bile acid sequestrants, such as cholestyramine and colestipol, and aluminum hydroxide (antacids) and sucralfate bind to exogenous T_4 and decrease GI absorption (Table 56–2). Because the evidence supporting their effectiveness is poor, they are not routinely recommended for thyroid hormone overdose.⁵⁸

Oral iodine containing contrast media is known to decrease peripheral conversion of T_4 to T_3 . Doses of 1 to 2.5 mg/kg iodine PO daily are routinely used for thyroid storm (oral drops commonly referred to as saturated solution potassium iodide {KI}). Thioamides, such as propylthiouracil (PTU) and methimazole, and the corticosteroids are thyroid gland inhibitors that are used for treatment of non drug related hyperthyroidism. In addition, thioamides inhibit peripheral conversion of T_4 to T_3 . Evidence from limited case reports suggests poor efficacy of both thioamides and corticosteroids in acute overdose^{8,25,58} (see Thioamides and Iodides).

Although use of antithyroid drugs such as PTU, corticosteroids, and iodine contrast media in thyroxine overdose has theoretical benefits, these xenobiotics are not validated, potentially harmful, and unlikely to offer additional benefit, or be superior to conventional therapy with activated charcoal, β -adrenergic antagonism, and sedation. These treatments are not recommended as adjunctive therapies for treatment of exogenous thyroxine overdose.

Extracorporeal Drug Removal

Extracorporeal drug removal procedures, such as plasma exchange or plasmapheresis, exchange transfusion (in children), and charcoal hemoperfusion, have been used in extreme cases of thyroid hormone overdose and thyroid storm.^{1,8,9,25,39,46,54,58,62,71,75,102,106} Overall, results regarding improvement of clinical condition and plasma clearances of thyroid hormones with these methods are conflicting. The largest series of acute ingestions involved six patients who became critically ill after massive thyroxine ingestions of prescribed capsules containing a 1000-fold concentration excess of thyroxine (dose range, 50,000–125,000 $\mu\text{g/day}$ for 2–12 days). Charcoal hemoperfusion and plasmapheresis were used in all patients. Plasmapheresis was found to be more effective than hemoperfusion in the extraction of thyroxine. The authors suggest this intervention may shorten the duration of thyrotoxicosis. Rebound elevations in plasma concentrations occurred 24 hours later, suggesting redistribution between extravascular and intravascular compartments.⁸ This redistribution is expected given the large volume of distribution for thyroid hormones (Table 56–1). There may be a role for early plasmapheresis in the exceptional situation of a known massive ingestion of thyroid hormone. Because the outcomes from most ingestions of thyroid hormone will be favorable with good supportive care, sedation, and β -adrenergic antagonism, the risks of plasmapheresis should be evaluated on a case by case basis after consultation with a medical toxicologist.

XENOBIOTICS WITH ANTITHYROID EFFECTS

Thioamides

Antithyroid drugs are used to decrease the amount of thyroid hormone in hyperthyroidism, most commonly in Graves disease. Thioamides are a group of chemicals with the basic structure of R-SCN. Methimazole and propylthiouracil (PTU) are the two principal thioamides used for treatment of hyperthyroidism. Carbimazole, which is bioactivated methimazole, is available in Europe and China. Methimazole and PTU both inhibit the activity of thyroid peroxidase in the thyroid gland.¹⁰³ PTU has the added effect of inactivating 5'-deiodinase, which decreases the peripheral conversion of T_4 to the metabolically more active T_3 .^{19,60} Because thioamides act primarily by decreasing thyroid hormone synthesis (vs release), a lag time of 3 to 4 weeks may occur before T_4 is depleted. The oral bioavailability of PTU is 50% to 80%. It is rapidly absorbed from the gastrointestinal tract and may undergo first-pass effect by the liver. Although its plasma half-life is only 1.5 hours, its effects are long lasting because of accumulation in the thyroid gland. PTU is inactivated by glucuronidation and is renally eliminated. Methimazole is completely absorbed, is concentrated in the thyroid, and is more slowly eliminated than PTU (48 vs 24 hours). Doses of PTU are in the range of 100 mg orally every 6 to 8 hours. Methimazole can be given 30 mg PO daily. Although PTU is 10 times less potent than methimazole, it is more commonly used. The indications for its use are mild-to-moderate hyperthyroidism.

The two thioamides traverse the placenta (methimazole more than PTU) and should not be administered during pregnancy. However, they are minimally secreted in breast milk. Adverse effects occur in 3% to 12% of patients taking thioamides. The most common adverse effect is a maculopapular pruritic rash. Methimazole, PTU, and, to a lesser extent, carbimazole can cause immune-mediated, dose-related, and age-related agranulocytosis and neutrophil dyscrasias.^{61,66,72,83}

This potentially life-threatening adverse effect can be treated by administration of granulocyte colony-stimulating factor.⁵ Premature withdrawal of thioamides can lead to rebound symptoms and thyrotoxic states.⁵⁵

There are little data regarding overdose with thioamides. A 12-year-old girl with a previous thyroidectomy, who was estimated to have ingested 5000 to 13,000 mg PTU, developed only a transient decreased T₃ concentration and elevated alkaline phosphatase concentration (7350 mU/mL).⁴⁴ The absence of a functioning thyroid gland may have contributed to the benign course in this patient. No other serious sequelae have been associated with acute overdose of thioamides.

Iodides

Prior to the development of thioamides, iodide salt was the principal treatment for hyperthyroidism. Iodides decrease thyroid hormone concentrations by inhibiting formation and release. In thyroid storm, high-dose iodides (>2 g/day) decrease thyroid hormone release and produce substantial improvements by 2 to 7 days. Common sources of iodides include calcium iodide, sodium iodide, KI (pharmaceutical preparations, iopanoic acid, Lugol solution {iodine + KI solution}, oral drops {saturated solution KI}), and methyl iodide (industrial preparations).

The adverse reaction to chronic ingestion of small or excessive amounts of iodide salts, termed iodism, is characterized by cutaneous rash, laryngitis, bronchitis, esophagitis, conjunctivitis, drug fever, metallic taste, “mumps,” salivation, headache, and bleeding diathesis. Immune-mediated hypersensitivity symptoms consisting of urticaria, angioedema, eosinophilia, vasculitis, arthralgia, lymphadenitis, and, rarely, anaphylactoid reactions may occur. Chronic iodide therapy has produced goiters, hypothyroidism, and rarely hyperthyroidism. As much as 10 g sodium iodide has been administered IV without development of signs or symptoms of toxicity.

Iodide (I⁻), unlike iodine (I₂), is not a caustic (Chaps. 104 and 106). KI is added to table salt to form iodized salt for prevention of goiter. It also is used prophylactically after exposure to large amounts of nuclear fallout to prevent uptake of radioactive iodine into the thyroid gland (Antidotes in Depth: A43) and is the most commonly used iodide for thyroid suppression in hyperthyroidism. Iodide mumps is a well-described but rare disorder characterized by severe sialadenitis (or parotitis),⁴⁷ allergic vasculitis, and/or conjunctivitis following administration of ionic and nonionic iodine-containing contrast media and oral iodide salts (Table 56–4).^{12,13,45} Although the mechanism remains unclear, it is thought to be idiosyncratic or secondary to iodide accumulation and subsequent inflammation in the ductal systems of the salivary gland. Clinical effects tend to occur within 12 hours and resolve spontaneously within 48 to 72 hours.¹²

Iodides should be avoided in pregnancy because they readily cross the placenta. Severe fetal complications, such as cretinism and death from respiratory failure secondary to obstructive goiter, are reported.^{21,40,67} Iodide salts are adsorbed to activated charcoal.

Methyl iodide is a methylating agent used in the chemical and pharmaceutical industry, as a reagent in microscopy, as a catalyst in production of organic lead compounds, as an etching agent, as a component in fire extinguishers, and formerly as a soil fumigant. Methyl iodide toxicity from inhalation is associated with early pulmonary congestion, lethargy, and acute kidney injury. It also is associated with delayed cerebellar degeneration, multifocal neuropathies (cranial nerve and spinal), parkinsonian symptoms, and late and persistent psychiatric symptoms (months to years).^{2,41} Chronic repeated overexposures have led to misdiagnoses such as multiple sclerosis. The toxicity is similar to that of the monohalomethanes (Chap. 111).

SUMMARY

- Despite the prevalence of thyroid disorders in the general population and the widespread use of levothyroxine, remarkably little morbidity and mortality associated with overdose from thyroid hormones is reported.
- Most children with unintentional exposures can be observed as outpatients for 5 to 10 days.
- Acute intentional ingestions in adults may result in severe symptoms that require management in an intensive care unit.
- Supportive care with sedation, cooling measures, and β -adrenergic antagonism are adequate in most cases.
- Chronic ingestions may produce more severe symptoms as they may present more insidiously or are complicated by thyroid storm.
- Clinicians should suspect exogenous thyroid hormone exposure in patients with thyrotoxicosis and suppressed TSH concentrations.

D. ANTIMICROBIALS

57 ANTIBACTERIALS, ANTIFUNGALS, AND ANTIVIRALS

Christine M. Stork

HISTORY AND EPIDEMIOLOGY

Antimicrobials, including antibacterials, antifungals, and antivirals, have significantly improved the clinical care of infected patients since the introduction of penicillin in the 1940s. The development of antimicrobial-resistant strains of these pathogens has continually expanded the number of antimicrobials necessary, and this has increased the overall potential for toxicity after use. Fortunately, toxicity due to acute overdose is limited and chronic therapeutic doses are safe in the majority of patients.

Most adverse effects related to antimicrobials occur as a result of iatrogenic complications rather than intentional overdose. The diverse origins of these complications include dose, route and decision errors, allergic reactions, adverse effects, and interactions. Prevention, in the form of process improvements and information regarding populations at risk for adverse effects, is continually required to minimize these untoward events. Dosing errors are prominent in neonates and infants, necessitating care and constant diligence on the part of health care professionals.

Antimicrobials are more commonly associated with allergic reactions than are other xenobiotics. The reason for this is unclear, but it may be a result of their high frequency of use, repeated intermittent prescriptive use, or environmental contamination. A complete allergy history is essential to minimize these adverse events in patients being considered for antimicrobial therapy.

Many adverse effects attributed to antimicrobials are difficult to predict even when given patient and population specific parameters. In some cases, an excipient is responsible for the adverse effect, as recognized with the adverse effects found in patients after the use of procaine penicillin G. Antimicrobials are involved in many common and severe xenobiotic interactions, primarily through the inhibition of metabolic enzymes. Patients being considered for antimicrobial therapy should be carefully assessed for the use of concomitant therapies, both prescription and nonprescription which may be pharmacokinetically or pharmacodynamically affected by the chosen antimicrobial.

PHARMACOLOGY AND TOXICOLOGY

Antimicrobial pharmacology is aimed at the destruction of microorganisms through the inhibition of cell cycle reproduction or the altering of a critical function within a microorganism. [Table 57–1](#) lists antimicrobials and their associated mechanisms of activity, toxicologic effects, and related toxicologic mechanisms. Often the mechanisms for toxicologic effects following acute overdose differ from the therapeutic mechanisms.

TABLE 57–1. Antimicrobial Pharmacology and Adverse Effects

Antimicrobial	Antimicrobial Mechanism of Action	Acute Overdose	Chronic Administration
Antibacterial			
Aminoglycosides	Inhibit 30s ribosomal subunit	Neuromuscular blockade—inhibit the release of acetylcholine from presynaptic nerve terminals and acts as an antagonist at acetylcholine receptors	Nephrotoxicity/ototoxicity—form an iron complex that inhibits mitochondrial respiration and causes lipid peroxidation
Penicillins, cephalosporins, and other β -lactams	Inhibit cell wall mucopeptide synthesis	Seizures—agonist at picrotoxin-binding site, causing GABA antagonism	Hypersensitivity—immune
Chloramphenicol	Inhibits 50s ribosomal subunit and inhibits protein synthesis in rapidly dividing cells	Cardiovascular collapse	"Gray baby syndrome" Same as mechanism of action
Fluoroquinolones	Inhibit DNA topoisomerase and DNA gyrase	Same as mechanism of action; bind to cations (Mg^{++}), seizures	Not entirely known; bind to cations (Mg^{++}); tendon rupture, hyperglycemia or hypoglycemia
Linezolid	Inhibits bacterial protein synthesis through inhibition of N-formylmethionyl-t RNA	None clinically relevant	MAOI activity; vasopressor response to tyramine; serotonin toxicity with SSRI and possibly meperidine
Macrolides, lincosamides, and ketolides	Inhibit 50s ribosomal subunit in multiplying cells	Prolong QT interval; blocks delayed rectifier potassium channel	Not entirely known; cytotoxic effect; exacerbation of myasthenia gravis
Nitrofurantoin	Bacterial enzymatic inhibitor	Gastritis	Dermatologic, hematologic, pancreatitis, parotitis, hepatitis, crystalluria, pulmonary fibrosis
Sulfonamides	Inhibit paraaminobenzoic acid and/or paraamino glutamic acid in the synthesis of folic acid	None clinically relevant	Hypersensitivity—metabolite acts as hapten leading to hemolysis/methemoglobinemia—exposure to UVB causes free radical formation
Tetracycline	Inhibits 30s and 50s ribosomal subunits; binds to aminacyl transfer RNA	None clinically relevant	Photosensitivity reaction
Vancomycin	Inhibits glycopeptidase polymerase in cell wall synthesis	"Red man syndrome"—anaphylactoid	Unknown
Antifungal			
Amphotericin B	Binds with ergosterol on cytoplasmic membrane to create pores to facilitate organelle leak	Same as mechanism of action	Nephrotoxicity—vehicle deoxycholate may be involved; nephrocalcinosis
Triazoles, imidazoles, and thiazoles	Increase permeability of cell membranes	None clinically relevant	None clinically relevant ?CYP inhibition

GABA = γ -aminobutyric acid; MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin reuptake inhibitor; UVB = ultraviolet light.

ANTIBACTERIALS

Aminoglycosides

Aminoglycoside that are in current use in the United States include amikacin, gentamicin, kanamycin, neomycin, paromomycin, streptomycin, and tobramycin.

Because aminoglycosides are only available in parenteral, topical, and ophthalmic forms, overdoses are almost exclusively the result of dosing errors. Fortunately, overdoses are rarely life threatening, and most patients can be safely managed with minimal intervention.^{24,121} The adverse effects of aminoglycosides are generally class based, although subtle differences may exist in the potency with which the adverse effects occur (Table 57–2).

TABLE 57–2. Predominant Manifestations of Aminoglycoside Toxicity

<i>Cochlear</i>	<i>Cochlear and Vestibular</i>	<i>Vestibular</i>	<i>Renal</i>
Kanamycin	Amikacin	Gentamicin	Amikacin
Neomycin	Tobramycin	Streptomycin	Gentamicin
			Kanamycin
			Neomycin
			Streptomycin
			Tobramycin

Large intravenous doses of aminoglycosides are both sufficiently safe and effective for use in single daily doses.⁶ Rarely, acute aminoglycoside overdose results in nephrotoxicity, ototoxicity, or vestibular toxicity.^{117,141} In one reported case, postmortem analysis confirmed complete loss of hair cells in the inner and outer cochlear (Chap. 26).

Aminoglycosides can exacerbate concomitant neuromuscular blockade, particularly at times corresponding to high peak serum aminoglycoside concentrations (Chap. 69).¹⁷¹ This is caused by inhibiting presynaptic calcium channels, thereby inhibiting the release of acetylcholine from presynaptic nerve terminals. Risk factors for enhanced neuromuscular blockade include patients with abnormal neuromuscular junction function, such as those with myasthenia gravis and botulism.

Adverse Effects Associated with Therapeutic Use. Adverse effects, including nephrotoxicity and ototoxicity, correlate more closely with elevated trough serum concentrations than with elevated peak concentrations.^{108,149} Less common adverse effects associated with chronic use include electrolyte abnormalities, allergic reactions, hepatotoxicity, anemia, granulocytopenia, thrombocytopenia, eosinophilia, retinal toxicity, reproductive dysfunction, tetany, and psychosis.^{55,112,126,217,233} When aminoglycosides are administered at high doses or during once-daily dosing, sepsislike chills and malaise may occur that can be the result of excipients delivered during the infusion.⁴⁶

Nephrotoxicity. The mechanism of nephrotoxicity and ototoxicity is incompletely understood, but appears to include the formation of reactive oxygen species in the presence of iron. Mitochondrial respiration is inhibited, lipid peroxidation occurs, and stimulation of glutamate activated N-methyl-D-aspartate (NMDA) receptors may play a role.^{96,243} The incidence of nephrotoxicity with aminoglycoside therapy is estimated at 5% to 10%.⁹ Although the aminoglycosides are almost completely excreted prior to biotransformation in the kidney, a small fraction of filtered aminoglycoside is transported by absorptive endocytosis across the apical membrane of proximal tubular cells where it becomes sequestered within lysosomes. The aminoglycoside then binds to and destroys phospholipids contained on brush border membranes in the proximal renal tubule.⁹

When this happens, acute tubular necrosis occurs after 7 to 10 days of standard-dose therapy. Laboratory abnormalities include granular casts, proteinuria, elevated urinary sodium, and increased fractional excretion of sodium. Usually acute kidney injury (AKI) that results is reversible; however, irreversible toxicity has been reported. Functionally, the injury occurs days prior to elevations in serum creatinine concentration, and for this reason a delay in diagnosis is common.²⁰⁴ Risk factors for the development of nephrotoxicity include increasing age, chronic kidney disease (CKD), female sex, previous aminoglycoside therapy, liver dysfunction, large total dose, long duration of therapy, frequent doses, high trough

concentrations, the presence of other nephrotoxic xenobiotics, and shock.^{9,152} Because the uptake of aminoglycosides into organs is saturable, appropriate once-daily high-dose regimens are less problematic than several lesser doses given in a single day.

Ototoxicity. Ototoxicity can occur after acute or prolonged exposure to aminoglycosides.²⁰⁶ Both cochlear and vestibular dysfunction occur and injury is thought to result from prolonged contact time with sensory hair cells after bioaccumulation in the endolymph and perilymph spaces.³ Vestibular toxicity, caused by destruction of sensory receptor portions of the inner ear or destruction of hair cells in the utricle and saccule, occurs in 0.4% to 10% of patients. Symptoms include vertigo or tinnitus. Table 57–2 details the relative characteristic toxicity of various aminoglycosides.

Full-tone audiometric testing may first show high-frequency hearing loss, which may subsequently progress. Given the inability of cochlear hair cells to regenerate, all hearing loss that develops is permanent. After early diagnosis of vestibular dysfunction, patients may improve after discontinuation of the xenobiotic. Simultaneous administration of other ototoxic xenobiotics enhances the ototoxicity of aminoglycosides (Chap. 26).

Withdrawal of the offending xenobiotic is indicated in patients with either nephrotoxicity or ototoxicity caused by an aminoglycoside antibiotic. Supportive care is the mainstay of therapy. Experimental treatments in animal models include the use of deferoxamine, glutathione, and NMDA-receptor antagonists in an attempt to chelate and or detoxify a reactive intermediate.^{165,221} The antibiotic ticarcillin forms a renally eliminated complex with aminoglycosides to provide protection against tobramycin-induced AKI. In humans, ticarcillin removes 50% more tobramycin in 48 hours than in two sessions of hemodialysis.⁷² However, ticarcillin therapy is generally of limited value because in most instances the serum concentration of the aminoglycoside has decreased before any therapeutic measures can be used.

Penicillins

Penicillin is derived from the fungus *Penicillium* and many semisynthetic derivatives have clinical utility. Penicillins, as a class, contain a 6-aminopenicillanic acid nucleus, composed of a β -lactam ring fused to a five-member thiazolidine ring. Classic available penicillins include penicillin G, penicillin V, and the antistaphylococcal penicillins (nafcillin, oxacillin, cloxacillin, and dicloxacillin). Penicillins developed to enhance the spectrum of antibiotic efficacy, particularly against Gram-negative bacilli, include the second generation penicillins (ampicillin, amoxicillin, bacampicillin, and mezlocillin), third generation penicillins (carbenicillin and ticarcillin), and fourth-generation penicillins (piperacillin). Table 57–1 lists the pharmacologic mechanism of penicillins.

Acute oral overdoses of penicillin-containing xenobiotics are usually not life threatening.²²⁶ The most frequent complaints following acute overdose are nausea, vomiting, and diarrhea.

Seizures occur in persons given large intravenous or cerebral intraventricular doses of penicillins.^{113,123,147} More than 50 million units intravenously in less than 8 hours are generally required to produce seizures in adults.²⁰⁹ Penicillin induced seizures appear to be mediated through the picrotoxin-binding site on the neuronal chloride channel near the γ -aminobutyric acid (GABA) binding site (Chap. 14). Binding of the penicillin produces an allosteric change in the receptor that prevents GABA from binding, resulting in a relative lack of inhibitory tone.⁵⁸ Penicillin analogs (such as imipenem) also cause seizures, presumably through a similar mechanism.

The treatment of patients who develop penicillin induced seizures include GABA agonists such as the benzodiazepines. Patients who receive an intraventricular overdose may require cerebrospinal fluid exchange or perfusion to attenuate seizure activity (Special Considerations: SC3).¹²³ There are rare reports of hyperkalemia resulting in electrocardiographic abnormalities after the rapid intravenous infusion of potassium penicillin G to patients with CKD and amoxicillin overdose resulting in frank hematuria and AKI.^{32,85}

Adverse Effects Associated with Therapeutic Use. Penicillins are associated with a myriad of adverse effects after therapeutic use, the most common of which are allergic reactions. Penicillins are commonly implicated in immune-related reactions such as bone marrow suppression, cholestasis, hemolysis, interstitial nephritis, and vasculitis.^{7,83,103,220} Rare effects include pemphigus after penicillin use and corneal damage after the use of methicillin.^{20,250}

Acute Allergy. Penicillins are the pharmaceuticals most commonly implicated in the development of acute anaphylactic reactions. Anaphylactic reactions are severe, life-threatening, immune-mediated (immunoglobulin E {IgE}) reactions involving multiple organ systems that typically occur immediately after exposure. Table 57–3 lists the classifications of

anaphylactic reactions. Anaphylaxis to penicillin typically occurs after IgE antibody formation, which requires prior exposure. Life-threatening clinical manifestations include angioedema, tongue and airway edema, bronchospasm, bronchorrhea, dysrhythmias, cardiovascular collapse, and cardiac arrest.⁷³ The pathophysiology of systemic anaphylaxis is complex and involves multiple pathways. IgE antibodies are cross linked on the surface of mast cells and basophils, resulting in local and systemic release of preformed mediators of anaphylactic response, including leukotrienes C₄ and D₄, histamine, eosinophilic chemotactic factor, and other vasoactive substances, such as bradykinin, kallikrein, prostaglandin D₂, and platelet-activating factor (Fig. 57–1).

TABLE 57–3. Classification of Anaphylactic Reactions

Grade	Description
I	Large local contiguous reaction (>15 cm)
II	Pruritus (urticaria) generalized
III	Asthma, angioedema, nausea, vomiting
IV	Airway (asthma, lingual edema, dysphagia, respiratory distress, laryngeal edema) Cardiovascular (hypotension, cardiovascular collapse)

FIGURE 57–1. Description of systemic anaphylaxis.

The incidence of penicillin hypersensitivity is 5% overall, with 1% of penicillin reactions resulting in anaphylaxis. The risk for a fatal hypersensitivity reaction after penicillin administration is two in 100,000 (0.002%) patient exposures.²⁴¹ All routes of penicillin administration can result in anaphylaxis; however, it occurs most commonly after intravenous administration.

Treatment is supportive with careful attention to airway, breathing, and circulation. Initial therapy for anaphylaxis includes epinephrine 0.01 mg/kg (≤ 0.5 mg) given as 1:1000 (1 mg/mL) dilution intramuscularly (IM) every 10 to 20 minutes. Epinephrine bronchodilates and increases cardiac output through β -adrenergic receptor stimulation. In addition, β -adrenergic receptor stimulation results in decreased peripheral vascular tone. Oxygen and inhaled β_2 -adrenergic agonists are warranted in severe cases, as are corticosteroids. H_1 -receptor antagonists may be sufficient in patients with mild allergic reactions who do not have pulmonary manifestations or airway concerns.

H_2 -receptor antagonism as a treatment for anaphylaxis is controversial. H_2 -receptors, when stimulated in the peripheral vasculature, cause vasodilation; in the heart, they cause positive inotropy, positive chronotropy, and coronary vasodilation; and in the lung, they cause increased mucus production.¹⁹⁹ Theoretically, H_2 -receptor antagonists can lead to a decrease in myocardial function at a time when H_1 -receptor stimulation is causing hypotension, coronary vasoconstriction, and bronchospasm. However, in vitro and animal models demonstrate decreases in coronary circulation and decreases in the overall anaphylactic response following administration of H_1 blockers.¹⁵ All H_2 -receptor antagonists are useful for the treatment of pruritus and flushing after acute allergic reactions involving the skin.^{15,151} Cimetidine use following anaphylaxis may result in clinical improvement, particularly hypotension and tachycardia.^{64,251} Available data indicate that treatment of anaphylaxis using H_2 -receptor antagonists should only be considered when other therapies have failed and the patient is adequately H_1 -receptor antagonized. Finally, glucagon may be of some benefit, particularly in patients who are maintained on β -adrenergic antagonists (Antidotes in Depth: A18).

Amoxicillin-Clavulanic Acid and Hepatitis. If cholestatic hepatitis develops, it occurs 1 to 6 weeks after initiation of therapy with amoxicillin-clavulanate.⁸ The incidence of hepatotoxicity typically is estimated at 1.1 to 2.7 per 100,000 prescriptions.⁸² The mechanism of hepatotoxicity is not clear, but may be related to clavulanate, a β -lactamase inhibitor used to prevent the bacterial destruction of β -lactam antimicrobials, or one of its metabolites. Treatment is supportive and clinical findings typically resolve after the discontinuation of therapy. However, prolonged hepatitis, ductopenia (vanishing bile duct syndrome), and pancreatitis rarely occur.^{48,184} Behavioral disturbances with disorientation, agitation, and visual hallucinations temporally related to use are also reported.¹⁷

Hoigne Syndrome and Jarisch-Herxheimer Reaction. The most common adverse effects occurring after administration of large intramuscular or intravenous doses of procaine penicillin G are the Hoigne syndrome and the Jarisch-Herxheimer reaction.^{110,146} The Hoigne syndrome is characterized by extreme apprehension and fear, illusions, or hallucinations; changes in auditory and visual perception, tachycardia, systolic hypertension, and, occasionally, seizures that begin within minutes of injection.²⁴⁰ These effects occur in the absence of signs or symptoms of anaphylaxis. The cause of this syndrome is unknown. Procaine is implicated as the etiology because of the similarity to events that occur after the administration of other local anesthetics known as the so-called “caine” reaction.^{200,211,236} Hoigne syndrome is six times more common in men than in women.²¹⁴ The reason for this increased prevalence is unclear, but autosomal dominance and influences of prostaglandin and thromboxane A_2 activity in this population may be responsible.¹²

The Jarisch-Herxheimer reaction is a self-limited reaction that develops within a few hours of antibiotic therapy for the treatment of spirochetal diseases such as syphilis or Lyme disease. Myalgias, chills, headache, rash, and fever spontaneously resolve within 18 to 24 hours, even with continued antibiotic therapy.²¹⁰ The pathogenesis of this reaction is likely either endotoxin induced from the lysed spirochete or cytokine elevation.¹⁷⁷ Antiinflammatory medications and immune modulators may offer some relief, but the optimal treatment is still unclear.

CEPHALOSPORINS

Cephalosporins are semisynthetic derivatives of cephalosporin C produced by the fungus *Acremonium*, previously called *Cephalosporium*. Cephalosporins have a ring structure similar to that of penicillins and are generally divided into first, second, third, fourth, and fifth generations based on their antimicrobial spectrum. First generation cephalosporins include cefadroxil, cefazolin, cephalexin, cephradine, and cephadrine. Second generation cephalosporins include cefaclor, cefamandole, cefonicid, cefotetan, cefoxitin, cefprozil, and cefuroxime. Third generation cephalosporins include cefdinir, ceftazidime, cefixime, ceftibuten, cefoperazone, ceftizoxime, cefotaxime, ceftriaxone, and cefpodoxime. The fourth generation cephalosporin is cefepime and the fifth generation cephalosporin is ceftaroline.

Effects occurring after acute overdose of cephalosporins resemble those occurring with penicillins. Some cephalosporins also have epileptogenic potential similar to penicillin.²⁴⁴ Case reports demonstrate seizures after inadvertent intraventricular administration.^{34,129,252} Management of cephalosporin overdose is similar to that of penicillin overdose. Table 57–1 lists the pharmacologic mechanism of cephalosporins.

Adverse Effects Associated with Therapeutic Use. Cephalosporins rarely cause an immune-mediated acute hemolytic crisis.⁷⁰ Cefaclor is the cephalosporin most commonly reported to cause systemic immune complex hypersensitivity or serum sickness, although this can occur with other cephalosporins.^{119,140} Also like penicillins, first-generation cephalosporins are associated with chronic toxicity, including interstitial nephritis and hepatitis.²⁴⁹ Cefepime is reported to cause reversible coma and seizures.^{1,218}

Cross-Hypersensitivity. The cephalosporins contain a six-member dihydrithiazine ring instead of the five-member thiazolidine penicillin ring. The extent of cross-reactivity between penicillins and cephalosporins in an individual patient is largely determined by the type of penicillin allergic response experienced by the patient. The incidence of anaphylaxis to cephalosporins is between 0.0001% and 0.1%, with a threefold increase in patients with previous penicillin allergy.¹²⁰ The overall cross-reactivity rate is approximately 1% between penicillin and a first- or second-generation cephalosporin. Cross-reactivity between penicillin and third-, fourth-, or fifth-generation cephalosporins is likely to be negligible due to a dissimilar antigenic side chain.⁴³ In fact, IgE directed against a methylene substituent linking the side chain to the penicillin molecule is identified.⁹⁵ These determinants are quite distinct among cephalosporins, which cause the pattern of cross-hypersensitivity among cephalosporins to be much less well defined than among the penicillins. Caution should be used when considering first- or second-generation cephalosporins in penicillin- or cephalosporin-allergic patients; however, if a risk-to-benefit analysis demonstrates a clear benefit to the patient without equivalent alternatives, the cephalosporin should be given.

N-methylthiotetrazole Side-Chain Effects. Cephalosporins containing an N-methylthiotetrazole (nMTT) side chain (moxalactam, cefazolin, cefoperazone, cefmetazole, cefamandole, cefotetan) have toxic effects unique to their group structure. As these cephalosporins undergo metabolism, they release free nMTT, which is responsible for their effects (Fig. 57–2).¹⁴⁸ Free nMTT inhibits the enzyme aldehyde dehydrogenase and, in conjunction with ethanol, can cause a disulfiramlike reaction (Chaps. 79 and 80).³⁸

FIGURE 57–2. Characteristic structures of cephalosporins emphasizing the nMTT side chain. nMTT = N-methylthiotetrazole.

The nMTT side chain is also associated with hypoprothrombinemia, although a causal relationship is controversial.⁹¹ It is thought that nMTT depletes vitamin K-dependent clotting factors by inhibition of vitamin K epoxide reductase.¹⁶⁷ In a study of children one month to one year of age who were maintained on a prolonged antibiotic regimen, a significant degree of vitamin K–depletion was found.²² Treatment of patients suspected of hypoprothrombinemia caused by these cephalosporins consists of fresh frozen plasma, if bleeding is evident, and vitamin K₁ in doses required to resynthesize vitamin K cofactors ([Chap. 60](#) and [Antidotes in Depth: A15](#)).

Other β -Lactam Antimicrobials

Included in this group are monobactams such as aztreonam and carbapenems such as imipenem and meropenem. [Table 57–1](#) lists the pharmacologic mechanism of these xenobiotics.

Effects occurring after acute overdose of other β -lactam antimicrobials resemble those occurring after penicillin exposure. Imipenem has epileptogenic potential in both overdose and therapeutic dosing (see [Adverse Effects Associated](#)

With Therapeutic Use).^{42,131} Management guidelines for other β -lactam overdoses are similar to those for penicillin overdoses.

Adverse Effects Associated with Therapeutic Use. The risk factors for imipenem-related seizures include central nervous system disease, prior seizure disorders, and abnormal kidney function.¹⁷³ The mechanism for seizures appears to be GABA antagonism (similar to the penicillins) in conjunction with enhanced activity of excitatory amino acids.^{62,224}

Cross-Hypersensitivity. Aztreonam is a monobactam that does not contain the antigenic components required for cross-allergy with penicillins, and generalized cross-allergenicity is not expected.²⁰² However, aztreonam cross-reacts in vitro with ceftriaxone, thought to be the result of the similarity in their side-chain structure.¹⁷⁵ Skin test manifested cross-allergenicity has also been noted between imipenem and penicillin, although the clinical incidence of adverse reactions is yet to be determined.²⁰¹

Trimethoprim-Sulfamethoxazole

Trimethoprim and sulfamethoxazole work as antibacterials in tandem effectively preventing tetrahydrofolic acid synthesis in bacterial cells. Significant toxicity after acute overdose is not expected; however, a myriad of effects occur after chronic therapeutic use. Hyperkalemia can result due to the ability of trimethoprim to competitively inhibit sodium channels in the distal nephron causing impairment in renal potassium excretion. Clinically significant hyperkalemia is reported in patients concurrently on other xenobiotics that increase potassium and among those with CKD.^{68,164} Other effects commonly reported after use of trimethoprim/sulfamethoxazole combinations include cutaneous allergic reactions, hematologic disorders, methemoglobinemia, hypoglycemia, rhabdomyolysis, and psychosis.

Trimethoprim also inhibits the renal tubular secretion of creatinine resulting in an increase in serum creatinine measurement.⁵⁹ This effect is thought to be dose related and ranges from 13% to 35% in patients with CKD. The rise in creatinine is independent of glomerular filtration rate and resolves upon drug discontinuation.

Chloramphenicol

Chloramphenicol was originally derived from *Streptomyces venezuelae* and is now synthetically produced. Antimicrobial activity is demonstrated against many Gram-positive and Gram-negative aerobes and anaerobes. Table 57–1 lists the pharmacologic mechanism of chloramphenicol.

Acute overdose of chloramphenicol commonly causes nausea and vomiting. Chloramphenicol inhibits protein synthesis in rapidly proliferating cells. Metabolic acidosis occurs as a result of the inhibition of mitochondrial enzymes, oxidative phosphorylation, and mitochondrial biogenesis.⁸¹ Infrequently, sudden cardiovascular collapse can occur 5 to 12 hours after acute overdoses. Cardiovascular compromise is more frequent in patients with serum concentrations higher than 50 $\mu\text{g/mL}$.^{81,154,231} Because concentrations are not readily available, all poisoned patients should be closely observed for at least 12 hours after exposure. Orogastric lavage may be useful for recent ingestions when the patient has not vomited, and activated charcoal 1 g/kg should be orally given.

Extracorporeal means of eliminating chloramphenicol are not usually required because of its rapid metabolism. However, both hemodialysis and charcoal hemoperfusion decrease serum chloramphenicol concentrations and may be of benefit in patients with large overdoses, or in patients with severe hepatic or renal dysfunction.^{80,150,215} Exchange transfusion also lowers serum chloramphenicol concentrations in neonates.²²³ Surviving patients should be closely monitored for signs of bone marrow suppression, which is usually dose dependent.

Adverse Effects Associated with Therapeutic Use. Chronic toxicity of chloramphenicol is similar to that which occurs following acute poisoning. The classic description of chronic chloramphenicol toxicity is the “gray baby syndrome.”¹⁵⁴ Children with this syndrome exhibit vomiting, anorexia, respiratory distress, abdominal distension, green stools, lethargy, cyanosis, ashen color, metabolic acidosis, hypotension, and cardiovascular collapse.

Approximately 90% of systemic chloramphenicol is metabolized via glucuronyl transferase, forming a glucuronide conjugate. The remainder is excreted renally unchanged. Infants, in particular, are predisposed to the gray baby syndrome because they have a limited capacity to form a glucuronide conjugate of chloramphenicol and, concomitantly, a limited ability to excrete unconjugated chloramphenicol in the urine.^{88,248}

There are two types of bone marrow suppression that occur after use of chloramphenicol. The most common type is

dose dependent and occurs with high serum concentrations of chloramphenicol.^{106,107,208} Clinical manifestations usually occur within several weeks of therapy and include anemia, thrombocytopenia, leukopenia, and, very rarely, aplastic anemia. Bone marrow suppression is generally reversible on discontinuation of therapy. A second type occurs through inhibition of protein synthesis in the mitochondria of marrow cell lines.¹⁵⁷ This type causes the development of aplastic anemia, which is not dose related, generally occurs in susceptible patients within 5 months of treatment and has an approximately 50% mortality rate (Chap. 22).^{69,255} The dehydro and nitroso bacterial metabolites of chloramphenicol injure human bone marrow cells through inhibition of myeloid colony growth, inhibition of DNA synthesis, and inhibition of mitochondrial protein synthesis.¹¹⁵

Other adverse effects associated with chloramphenicol include peripheral neuropathy, neurologic abnormalities (eg, confusion, delirium), optic neuritis, nonlymphocytic leukemia, and contact dermatitis.^{52,124,133,180,213}

Fluoroquinolones

Ciprofloxacin

The fluoroquinolones are a structurally similar, synthetically derived group of antimicrobials that have diverse antimicrobial activities. They include balofloxacin, ciprofloxacin, clinafloxacin, enoxacin, fleroxacin, gatifloxacin, gemifloxacin, grepafloxacin, levofloxacin, lomefloxacin, moxifloxacin, nadifloxacin, nalidixic acid, norfloxacin, ofloxacin, pefloxacin, rufloxacin, sparfloxacin, temafloxacin, and tosufloxacin. Like other antimicrobials, the fluoroquinolones rarely produce life-threatening effects following acute overdose, and most patients can be safely managed with minimal intervention.¹¹ Table 57–1 lists the pharmacologic mechanism of fluoroquinolones.

Rarely, acute overdose of a fluoroquinolone results in AKI or seizures.¹²⁷ The mechanism of AKI after fluoroquinolone exposure is controversial. In animals, ciprofloxacin and norfloxacin are nephrotoxic, especially in the setting of neutral or alkaline urine.^{54,205} In humans, AKI is reported after both acute and chronic exposure to fluoroquinolones. A hypersensitivity reaction is postulated to explain pathologic changes consistent with interstitial nephritis.^{104,187} Treatment includes discontinuation of the fluoroquinolone and supportive care. Improvement in kidney function usually occurs within several days.

Seizures are reported with ciprofloxacin and may be a result of the inhibition of GABA or elevation of neuronal glutamate.^{2,216,235} Others postulate that seizures result from the ability of fluoroquinolones to bind efficiently to cations, particularly magnesium. This hypothesis is related to the inhibitory role of magnesium at the excitatory NMDA-gated ion channel (Chap. 14).⁶³ Treatment is supportive, using benzodiazepines and, if necessary, barbiturates to increase inhibitory tone.

Adverse Effects Associated with Therapeutic Use. Several fluoroquinolones are substrates and/or inhibitors of cytochrome CYP enzymes. This can result in xenobiotic interactions, which are especially important with xenobiotics that have a narrow therapeutic index.

Serious adverse effects related to fluoroquinolone use consist of central nervous system toxicity, as discussed, cardiovascular toxicity, hepatotoxicity, and notable musculoskeletal toxicity.

Fluoroquinolones cause prolongation of the QT interval, and they may also cause torsade de pointes.¹⁹⁵ Prolongation is due to the ability of fluoroquinolones to block the rapid component of the delayed rectifier potassium current (I_{Kr}). Treatment of patients presenting with QT prolongation is supportive.

Fluoroquinolones also rarely result in potentially fatal hepatotoxicity.¹³⁶ This adverse effect is most notable with trovafloxacin, which was withdrawn from the US market.

Fluoroquinolones should be used with caution in children and pregnant women because of their potential adverse effects on developing cartilage and bone.¹¹⁸ Damage is more common to fluoroquinolones with fleroxacin, pefloxacin, levofloxacin, and ofloxacin due to a substitution at the R-7 position of the quinolone core structure. There are very limited data regarding damage to articular cartilage as a result of using fluoroquinolones in humans; however, children given ciprofloxacin on a compassionate basis developed complaints of swollen, painful, and stiff joints after 3 weeks of

therapy.¹¹⁴ All signs and symptoms abated within 2 weeks of discontinuation of therapy. However, 29 additional children treated with ofloxacin or ciprofloxacin showed no differences with respect to cartilage thickness, cartilage structure, edema, cartilage-bone borderline, or synovial fluid.⁵⁷ Women who received quinolones during pregnancy had larger babies and more caesarean deliveries because of fetal distress than did controls.¹⁹

Fluoroquinolones are implicated as a cause of tendon rupture, which is reported to occur for months to one year after the start of treatment as well as after the discontinuation of therapy.^{174,219} The fluoroquinolone should be discontinued in patients, particularly in athletes who complain of symptoms consistent with painful and swollen tendons.

Other adverse effects include acute psychosis, hyperglycemia, hypoglycemia, rash, tinnitus, eosinophilia, serum sickness, and photosensitivity.^{39,92,155,172,222}

Macrolides and Ketolides

Erythromycin

The macrolide antimicrobials include various forms of erythromycin (base, ethylsuccinate, gluceptate, lactobionate, stearate), azithromycin, clarithromycin, dirithromycin, fidaxomicin, and troleandomycin. Ketolides are similar in pharmacology to macrolides; telithromycin is the only available agent at this time. [Table 57-1](#) lists the pharmacologic mechanism of macrolides and ketolides.

Acute oral overdoses of macrolide antimicrobials are not life threatening and symptoms, which are generally confined to the gastrointestinal tract, include nausea, vomiting, and diarrhea. However, intravenous overdoses can cause dysrhythmias.²²⁸

Intravenous and oral therapeutic use of macrolides cause QT interval prolongation and dysrhythmias. The QT interval prolongation seen occurs due to blockade of delayed rectifier potassium currents (I_{Kr} ; Chaps. 16 and 64).¹⁹⁴ Erythromycin lactobionate causes QT interval prolongation and torsade de pointes after intravenous use.¹⁶⁸ Oral erythromycin is also implicated in causing prolongation of the QT interval and torsade de pointes, especially in patients concurrently taking cytochrome (CYP3A4) inhibitors, in women, and in those with underlying heart disease.^{66,94,181} Oral use of azithromycin is associated with an increased risk of cardiovascular death with several case reports of QT interval prolongation, torsade de pointes, and polymorphic ventricular tachycardia.¹⁸⁰ In children, intravenous overdoses of azithromycin result in similar findings.

Although there are no acute overdose data regarding ketolide antimicrobials, effects are expected to be similar to macrolide antimicrobials. Therapeutic use of telithromycin is reported to result in QT interval prolongation, hepatotoxicity, toxic epidermal necrolysis, and anaphylaxis.³⁵

Adverse Events Associated with Interactions with Xenobiotics. Erythromycin is the prototypical macrolide and, as such, has received the most attention with respect to potential and documented xenobiotic interactions. Clarithromycin, erythromycin, and troleandomycin are all potent inhibitors of the CYP3A4 enzyme system; azithromycin does not inhibit this enzyme.⁵⁶ Erythromycin inhibits cytochrome P450 after metabolism to a nitroso intermediate, which then forms an inactive complex with the iron (II) of cytochrome P450. The appendix to [Chap. 13](#) lists substrates for the CYP3A4 system. Clinically significant interactions occur with erythromycin and warfarin, carbamazepine, or cyclosporine.^{40,99,178} Inhibition of cisapride metabolism results in increased concentrations of the parent xenobiotic, which is capable of causing prolongation of the QT interval and causing torsade de pointes.²⁹ Cases of carbamazepine toxicity are documented when combined with the use of erythromycin.⁹⁹ Erythromycin also inhibits CYP1A2, producing clinically significant interactions

with clozapine, theophylline, and warfarin.¹⁹⁰

Macrolides may also interact with the absorption and renal excretion of xenobiotics that are amenable to intestinal P-glycoprotein excretion, or interfere with normal gut flora responsible for metabolism. This may be part of the underlying mechanism of cases of macrolide-induced digoxin toxicity (Chap. 65).¹⁶⁶

End-organ effects. The most common toxic effect of macrolides after chronic use is hepatitis, which may be immune mediated.⁴⁴ Erythromycin estolate is the macrolide most frequently implicated in causing cholestatic hepatitis.^{87,111}

Large doses (> 4 g/day) of macrolide antimicrobials are also associated with reversible high-frequency sensorineural hearing loss.³⁶ Renal impairment may be a risk factor.^{198,225} There are rare case reports in which ototoxicity did not resolve following discontinuation of therapy.¹³² Other, rare toxic effects associated with macrolides include cataracts after clarithromycin use in animals and acute pancreatitis in humans.^{75,239} Allergy is rare and reported at a rate of 0.4% to 3%.⁶⁰ Telithromycin contains a carbamate side chain that may interfere with the normal function of neuronal cholinesterase. It should be used cautiously in patients with myasthenia gravis, particularly patients receiving pyridostigmine because of the risk of cholinergic crisis.²²⁹

Clindamycin is a lincosamide with similar structure and clinical effects to macrolides. Clindamycin phosphate is commonly used topically while clindamycin hydrochloride is available for intravenous use. Data regarding acute overdose are limited and most cases of chronic toxicity occur after use of systemic doses of clindamycin phosphate. The most consequential toxicity is gastrointestinal resulting in esophageal ulcers, diarrhea, and *C. difficile* mediated enterocolitis.¹⁸⁸

Sulfonamides

Sulfamethoxazole

Sulfonamides antagonize para-aminobenzoic acid or paraaminobenzyl glutamic acid, which are required for the biosynthesis of folic acid. Table 57–1 lists the pharmacologic mechanism of sulfonamides. Acute oral overdoses of sulfonamides are usually not life threatening, and symptoms are generally confined to nausea, although allergy and methemoglobinemia occur rarely.⁷⁹ Treatment is similar to acute oral penicillin overdoses.

Adverse Effects Associated with Therapeutic Use. The most common adverse effects associated with sulfonamide therapy are nausea and cutaneous hypersensitivity reactions. Hypersensitivity reactions are thought to be caused by the formation of hapten sulfamethoxazole metabolites, N-hydroxy-sulfamethoxazole and nitroso-sulfamethoxazole. The degree of hapten binding is mitigated in vitro by cysteine and glutathione.¹⁵⁸ The incidence of adverse reactions to sulfonamides, including allergy, is increased in HIV-positive patients and is positively correlated to the number of previous opportunistic infections experienced by the patient.¹³⁰ This may be caused by a decrease in the mechanisms available for detoxification of free radical formation, as cysteine and glutathione concentrations are low in these patients.²⁴⁶ Whether supplementation with a glutathione precursor such as N-acetylcysteine will reduce the incidence of these reactions is unknown.⁴

Methemoglobinemia and hemolysis occur rarely.^{67,159} The mechanism for adverse reactions is not entirely clear. However, when sulfamethoxazole is exposed to ultraviolet B radiation in vitro, free radicals are formed that can participate in the development of tissue peroxidation and hemolysis.²⁵⁵ This finding may be of particular importance in treating patients with glucose-6-phosphate dehydrogenase deficiency associated with decreased in reducing capabilities.⁵

The sulfonamides are associated with many chronic adverse effects. Bone marrow suppression is rare, but the incidence is increased in patients with folic acid or vitamin B₁₂ deficiency, and in children, pregnant women, alcoholics, dialysis patients, and immunocompromised patients, as well as in patients who are receiving other folate antagonists. Other adverse effects include hypersensitivity pneumonitis, stomatitis, aseptic meningitis, hepatotoxicity, renal toxicity, and central nervous system toxicity.²⁵

Tetracyclines

Tetracycline

Tetracyclines are derivatives of *Streptomyces* cultures. Currently available tetracyclines include demeclocycline, doxycycline, methacycline, minocycline, oxytetracycline, and tetracycline. Table 57–1 lists the pharmacologic mechanism of tetracyclines. Significant toxicity after acute overdose of tetracyclines is unlikely. Gastrointestinal effects consisting of nausea, vomiting, and epigastric pain have been reported.³⁷

Adverse Effects Associated with Therapeutic Use. Tetracycline should not be used in children during the first 6 to 8 years of life or by pregnant women after the 12th week of pregnancy because of the risk of development of secondary tooth discoloration in children or developing children in utero. Tooth discoloration can be effectively removed using topical application of carbamide peroxide whitening treatments.²³⁴ Other effects associated with tetracyclines include nephrotoxicity, hepatotoxicity, skin hyperpigmentation in sun-exposed areas, and hypersensitivity reactions.^{44,90,109,227} More severe hypersensitivity reactions, xenobiotic-induced lupus, and pneumonitis are reported after minocycline use, as are cases of necrotizing vasculitis of the skin and uterine cervix, and lymphadenopathy with eosinophilia.^{143,207,212} Demeclocycline rarely causes nephrogenic diabetes insipidus (Chaps. 19 and 28).⁴⁵

Vancomycin

Vancomycin

Vancomycin is obtained from cultures of *Nocardia orientalis* and is a tricyclic glycopeptide. Vancomycin is biologically active against numerous Gram-positive organisms. Table 57–1 lists the pharmacologic mechanism of vancomycin.

Acute oral overdoses of vancomycin rarely cause significant toxicity and most cases can be treated with supportive care alone. After large iatrogenic rapidly infused intravenous overdoses, AKI can occur in patients with preexisting kidney disease due to sustained high serum concentrations. In these patients, multiple doses of activated charcoal and potentially high-flux hemodialysis can be considered to enhance clearance.^{125,238}

Adverse Effects Associated with Therapeutic Use. Patients who receive intravenous vancomycin may develop the “red man syndrome” through an anaphylactoid (non-IgE-mediated) mechanism.⁸⁴ Symptoms include chest pain, dyspnea, pruritus, urticaria, flushing, and angioedema.¹⁹³ Signs and symptoms spontaneously resolve, typically within 15 minutes. Other symptoms attributable to “red man syndrome” include hypotension, cardiovascular collapse, and seizures.^{13,162}

The incidence of red man syndrome appears to be related to the rate of infusion and is approximately 14% when 1 g is given over 10 minutes, and falls dramatically to only 3.4% when given over 1 hour.^{162,169} A trial in 11 healthy persons

studied the relationship between intradermal skin hypersensitivity and the development of red man syndrome. Each of the 11 study participants underwent skin testing that was followed one week later by an intravenous dose of vancomycin 15 mg/kg over 60 minutes. Following intravenous vancomycin, all participants developed dermal flare responses and erythema, and 10 of 11 participants developed pruritus within 20 to 45 minutes. After the infusion was terminated, symptoms resolved within 60 minutes.¹⁷⁶

The signs and symptoms of this syndrome are related to the rise and fall of histamine concentrations.^{134,200} Tachyphylaxis occurs in patients given multiple doses of vancomycin.^{97,245} Animal models demonstrated a direct myocardial depressant and vasodilatory effect of vancomycin.⁵³ More serious reactions result when vancomycin is given via intravenous bolus, further supporting a rate-related anaphylactoid mechanism.²¹

Patients most often experience red man syndrome after vancomycin is administered intravenously. In rare cases, oral administration of vancomycin can also result in the syndrome.¹⁸ Treatment includes increasing the dilution of vancomycin and slowing intravenous administration. Antihistamines may be useful as pretreatment, especially prior to the first dose.¹⁸³ A placebo-controlled trial in adult patients studied the incidence of these symptoms in patients given 1 g of vancomycin over one hour, as well as the effect of diphenhydramine in the prevention of the syndrome.²⁴⁵ There was a 47% incidence of reaction without diphenhydramine and a 0% incidence with diphenhydramine.

Chronic use of vancomycin may cause reversible nephrotoxicity, particularly in patients with prolonged excessive steady-state serum concentrations.^{10,186} Concomitant administration of aminoglycoside antimicrobials may increase the risk of nephrotoxicity.¹⁹⁶ Vancomycin also causes, though rarely, thrombocytopenia and neutropenia.^{50,51,65}

ANTIFUNGALS

Numerous antifungals are available. Toxicity related to the use of antifungals is variable and is based generally on their mechanism of action.

Amphotericin B

Amphotericin B is a potent antifungal derived from *Streptomyces nodosus*. Amphotericin B is generally fungistatic against fungi that contain sterols in their cell membrane. Table 57–1 lists the pharmacologic mechanism of amphotericin B. Development of lipid and colloidal formulations of amphotericin B attenuate the adverse effects associated with amphotericin B.⁹³ In these preparations, the amphotericin B is complexed with either a lipid or cholesteryl sulfate. On contact with a fungus, lipases are released to free the complexed amphotericin B, resulting in focused cell death.¹⁰¹

There are several case reports of amphotericin B overdose in infants and children. Significant clinical findings include hypokalemia, increased aspartate aminotransferase concentrations, and cardiac complications. Dysrhythmias and cardiac arrest have occurred following doses of 5 to 15 mg/kg of amphotericin B.^{31,51,122} Care should be used in the doses of amphotericin B administered according to specific formulation design, as these are not interchangeable. For example, intravenous therapy for fungal infections includes a usual dose of 0.25 to 1 mg/kg/day of amphotericin B or 3 to 4 mg/kg/day of amphotericin B cholesteryl. The potential for significant dosage errors and their sequelae is readily apparent in this comparison.

Adverse Effects Associated with Therapeutic Use. Infusion of amphotericin B results in fever, rigors, headache, nausea, vomiting, hypotension, tachycardia, and dyspnea.¹⁴⁴ Pretreatment with acetaminophen, diphenhydramine, ibuprofen, and hydrocortisone is helpful in alleviating the febrile symptoms, as are slower rates of infusion and lower total daily doses.^{86,237} Doses greater than 1 mg/kg/day and rapid administration in less than 1 hour are not recommended. Infusion concentrations of amphotericin B greater than 0.1 mg/mL can result in localized phlebitis. Slower infusion rates, hot packs, and frequent line flushing with dextrose in water may help to alleviate symptoms.

A total of 80% of patients exposed to amphotericin B will sustain some degree of kidney dysfunction (Chap. 28).⁴¹ Initial distal renal tubule damage causes renal artery vasoconstriction ultimately resulting in azotemia.⁷⁶ Studies in animals show depressed renal blood flow and glomerular filtration rate, and increased renal vascular resistance. It is unclear why

this occurs, but at this time, renal nerves, angiotensin II, nitric oxide, and tubuloglomerular feedback are excluded.^{197,203} The toxic effects associated with amphotericin B may also be caused by the deoxycholate vehicle.²⁵⁴ After large total doses of amphotericin B, residual decreases in glomerular filtration rate may occur even after discontinuation of therapy. This is hypothesized to be the result of nephrocalcinosis. Potassium and magnesium wasting, proteinuria, decreased renal concentrating ability, renal tubular acidosis, and hematuria can also occur (Chaps. 19 and 28).^{14,144} Strategies to reduce renal toxicity after amphotericin B include intravenous saline or magnesium and potassium supplementation.^{28,77,100} Liposomal formulations of amphotericin B resulted in fewer patients with breakthrough fungal infections, infusion-related fever, rigors, or nephrotoxicity.²⁴⁷ However, chest pain is uniquely reported after use of the liposomal preparation.¹¹⁶

Other adverse effects reported after treatment with amphotericin B include normochromic, normocytic anemia secondary to decreased erythropoietin release; respiratory insufficiency with infiltrates; and, rarely, dysrhythmias, tinnitus, thrombocytopenia, peripheral neuropathy, and leukopenia.^{135,142,144}

Exchange transfusion may be useful in neonates and infants and should be considered after large intravenous doses. In adults, extracorporeal elimination is not expected to be useful because of the low water solubility and high blood-protein binding of the xenobiotic.

Azole Antifungals: Triazole, Imidazoles, and Thiazoles

Triazole antifungals include fluconazole, fosfluconazole, hexaconazole, itraconazole, posaconazole, terconazole, and voriconazole. Common imidazoles include clotrimazole, econazole, ketoconazole, and miconazole. Abafungin is a thiazole. Triazole antifungals treat an array of fungal pathogens, whereas imidazoles and thiazoles are used almost exclusively in the treatment of superficial mycoses and vaginal candidiasis. Severe toxicity is not expected in the overdose setting. Hepatotoxicity, thrombocytopenia, and neutropenia are uncommon.²⁶ Rare case reports implicate voriconazole in the development of toxic epidermal necrolysis.¹⁰⁵ Most of the toxic effects noted after the use of these xenobiotics result from their xenobiotic interactions. Fluconazole, itraconazole, ketoconazole, and miconazole competitively inhibit CYP3A4, the isoenzyme system responsible for the metabolism of many xenobiotics. Table 57–4 lists other organ system manifestations associated with antifungal agents and other antimicrobials.

TABLE 57–4. Major Organ System Manifestations Associated with Antimicrobial Toxicity

<i>Antimicrobial</i>	<i>System</i>	<i>Signs/Symptoms/Laboratory Findings</i>
Antibacterials		
Bacitracin	Immune	Hypersensitivity reactions
Clindamycin	Immune	Hypersensitivity reactions
	Gastrointestinal	Nausea, vomiting, diarrhea
	Neurologic	Dizziness, headache, vertigo
Colistimethate (colistin sulfate)	Renal	Decreased function, acute tubular necrosis
	Neurologic	Peripheral paresthesias, confusion, coma, seizures, neuromuscular blockade
Metronidazole	Neurologic	Peripheral neuropathy, seizures
	Gastrointestinal	Nausea, vomiting
	Other	Disulfiram reactions
Nitrofurazone	Immune	Hypersensitivity reactions
	Other	Ointment contains polyethylene glycols (renal dysfunction)
Nitrofurantoin	Gastrointestinal	Nausea, vomiting, diarrhea
	Hepatic	Jaundice
	Immune	Rash, acute and chronic pulmonary hypersensitivity
Novobiocin	Neurologic	Peripheral neuropathy
	Immune	Rash
	Gastrointestinal	Nausea, vomiting, diarrhea
	Hematologic	Pancytopenia, hemolytic anemia
Polymyxin B sulfate	Neurologic	Muscle weakness, seizures
	Renal	Azotemia, proteinuria
Selenium sulfide	Cutaneous	Contact dermatitis, alopecia (rare)
Silver sulfadiazine	Cutaneous	Contact dermatitis
	Hematologic	Anemia, aplastic anemia
Spectinomycin	Immune	Rash (rare)
Antifungals		
Benzoic acid	Gastrointestinal	Nausea, vomiting, diarrhea
Carbol-fuchsin solution (phenol/resorcinol/fuchsin)	Gastrointestinal	Nausea, vomiting, diarrhea
Gentian violet	Gastrointestinal	Nausea, vomiting, diarrhea
	Immune	Rash (rare)
Griseofulvin	Renal	Proteinuria, nephrosis
	Hepatic	Increased enzymes
	Gastrointestinal	Nausea, vomiting, diarrhea
	Immune	Neutropenia
	Other	Disulfiram reactions, increased porphyrins
Nystatin	Gastrointestinal	Nausea, vomiting, diarrhea
Salicylic acid	Gastrointestinal and dermal	Higher concentrations are caustic
Undecylenic acid and undecylenate salt	Gastrointestinal	Nausea, vomiting, diarrhea

ANTIPARASITICS

Antiparasitics such as thiabendazole, mebendazole, albendazole, diethylcarbazine, ivermectin, metrifonate, niclosamide, oxfamniquine, piperazine, praziquantel, and pyrantel pamoate generally have limited toxicity in the overdose. Common symptoms after therapeutic use are gastrointestinal in nature and include abdominal pain, nausea, vomiting, and diarrhea. A single case of ivermectin associated hepatic failure is reported one month after a single dose.²⁴²

Antiviral

Acyclovir and valacyclovir are generally well tolerated in therapeutic doses and overdoses. In 105 dogs ingesting 40 to 2195 mg/kg, gastrointestinal symptoms were most common, with one dog developing mild creatinine increases.¹⁸⁵ A single case report describes AKI with crystalluria after ingestion of 30 g of valacyclovir.¹⁸⁹ Depressed mental status and nephrotoxicity are also reported after therapeutic use in humans.²⁷

ANTIMICROBIALS SPECIFIC TO THE TREATMENT OF HIV AND RELATED INFECTIONS

The evaluation and management of patients infected with HIV/AIDS continues to dramatically evolve. Medications used to manage this disorder have increased life expectancy as new, more powerful antivirals and xenobiotic combinations become available. Xenobiotic therapy for HIV commonly consists of a combination of xenobiotics from different classes (nucleoside reverse transcriptase inhibitor {NRTI}, nonnucleoside reverse transcriptase inhibitor, protease inhibitor, integrase inhibitor, fusion inhibitor, and C-C chemokine receptor type 5 {CCR5} antagonist) to utilize the advantages of the unique mechanisms that each xenobiotic offers in inhibiting viral replication and minimizing xenobiotic resistance. Drug and dosage errors, particularly in infants, are of significant concern and have resulted in iatrogenic overdose.^{30,49,138} This section focuses on overdoses and major toxic effects from HIV directed antiviral therapy, as well as from xenobiotics that are specifically used in the management of opportunistic infections.²³⁰ A comprehensive review of these medications and currently recommended use patterns, drug interactions, and end-organ toxicities can be found at <http://aidsinfo.nih.gov/guidelines>. Table 57–5 lists the common antimicrobials used to treat HIV-related opportunistic infections, and Table 57–6 lists common adverse xenobiotic effects and overdose effects, if known, for antimicrobials that are specific in their use for HIV-related infections.

TABLE 57–5. Antimicrobials Used to Treat Common Opportunistic Infections

<i>Antimicrobial</i>	<i>Opportunistic Infection</i>
Albendazole	Microsporidiosis
Amphotericin B	Aspergillosis Candidiasis Coccidioidomycosis Cryptococcosis Histoplasmosis Leishmaniasis Paracoccidioidomycosis Penicilliosis
Antimony (pentavalent)	Leishmaniasis
Atovaquone	<i>Pneumocystis jiroveci</i>
Azithromycin	<i>Mycobacterium avium</i> complex
Clarithromycin	<i>Mycobacterium avium</i> complex
Caspofungin	Aspergillosis
Clindamycin	<i>Pneumocystis jiroveci</i> <i>Toxoplasma gondii</i>
Dapsone	<i>Pneumocystis jiroveci</i>
Ethambutol	<i>Mycobacterium avium</i> complex
Fluconazole	Coccidioidomycosis Histoplasmosis
Flucytosine	Cryptococcosis
Foscarnet	Cytomegalovirus
Fumagillin	Microsporidiosis
Ganciclovir	Cytomegalovirus
Itraconazole	Histoplasmosis
Nitazoxanide	Cryptosporidiosis Microsporidiosis
Paromomycin	Cryptosporidiosis
Pentamidine	<i>Pneumocystis jiroveci</i>
Primaquine	<i>Pneumocystis jiroveci</i>
Pyrimethamine	<i>Toxoplasma gondii</i>
Rifabutin	<i>Mycobacterium avium</i> complex
Sulfadiazine	<i>Toxoplasma gondii</i>
Trimethoprim/sulfamethoxazole	<i>Pneumocystis jiroveci</i> <i>Toxoplasma gondii</i> Isosporiasis
Trimetrexate	<i>Pneumocystis jiroveci</i>
Valganciclovir	Cytomegalovirus
Voriconazole	Aspergillosis

TABLE 57–6. Toxicity of Antimicrobials Used in the Treatment of HIV Related Infections

Antimicrobial	Overdose Effects	Common Adverse Drug Effects
Albendazole	No reported cases	Increased AST/ALT, nausea, vomiting, and diarrhea; hematologic (rare), encephalopathy, AKI, rash
Antimony (pentavalent)	AKI	AKI, multiorgan system failure
Atovaquone	No clinical effects	Rashes, anemia, leukopenia, increased AST/ALT
Caspofungin	No reported cases	Phlebitis, headache, hypokalemia, increased AST/ALT, fever
Flucytosine	No reported cases	Bone marrow suppression, hepatotoxicity, nausea, vomiting, diarrhea, rash
Foscarnet	No reported cases	Azotemia, hypocalcemia, and kidney failure (common); anemia, leukopenia, thrombocytopenia, fever, headache, seizures, genital and oral ulcers, food-drug eruptions, nausea, vomiting, diarrhea, headaches, seizures, coma, diabetes insipidus, hypophosphatemia, hypokalemia, hypomagnesemia
Fumagillin	No reported cases	Neutropenia, thrombocytopenia
Ganciclovir	No clinical effects	Leukopenia, worsening of kidney function; can also cause nausea, vomiting, diarrhea, increased AST/ALT, anemia, thrombocytopenia, headache, dizziness, confusion, seizures
Nitazoxanide	No reported cases	Hypotension, headache, abdominal pain, nausea, vomiting; may cause green-yellow urine discoloration
Pentamidine	40 times dosing error in a 17 month-old child resulted in cardiac arrest	Hypoglycemia (early) followed by hyperglycemia, azotemia; can cause hypotension, torsade de pointes, phlebitis, rash, Stevens-Johnson syndrome, hypocalcemia, hypokalemia, anemia, nausea, vomiting, metallic taste, leukopenia, thrombocytopenia
Primaquine	No reported cases	Neutropenia, hemolytic anemia, methemoglobinemia, leukocytosis, hypertension
Pyrimethamine	No reported cases	Agranulocytosis, aplastic anemia, thrombocytopenia, leukopenia
Rifabutin	High doses (> 1 g daily): arthralgia/arthritis	Nausea, vomiting, diarrhea; can cause hepatotoxicity, neutropenia, thrombocytopenia, hypersensitivity reactions
Sulfadiazine	AKI and hypoglycemia	Rash, Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema multiforme; headaches, depression, hallucinations, ataxia, tremor, crystalluria, hematuria, proteinuria, and nephrolithiasis
Trimethopate	No reported cases; treat similarly to methotrexate (Chap. 51)	Myelosuppression, nausea, vomiting, histaminergic reactions
Valganciclovir	No reported cases; expect to be similar to ganciclovir	Anemia, neutropenia, thrombocytopenia; nausea, vomiting, headache, peripheral neuropathy

AKI = acute kidney injury; ALT = alanine aminotransferase; AST = aspartate aminotransferase.

Specific Antiretroviral Classes

Nucleoside Analog Reverse Transcriptase Inhibitors. The nucleoside analog reverse transcriptase inhibitors inhibit the reverse transcription of viral RNA into proviral DNA. Currently available xenobiotics include abacavir, emtricitabine, didanosine (ddI), lamivudine, stavudine, telbivudine, and zidovudine.

Acute overdose effects. Many intentional overdoses of reverse transcriptase inhibitors occur without major toxicologic effect. The most serious adverse effect anticipated after acute overdose of an NRTI is the development of a metabolic acidosis with elevated lactate concentration, which appears to be more common in women.^{47,74,145} Following incorporation of the nucleoside analog into mitochondrial DNA by RNA polymerase, DNA polymerase γ is inhibited. This results in decreased production of mitochondrial DNA electron transport proteins, which ultimately inhibits oxidative phosphorylation (Chaps. 13 and 23). Organ system toxicity follows in addition to the development of acidemia. The reported mortality in patients with NRTI-associated metabolic acidosis associated with elevated lactate is 33% to 57%.⁷⁴ Resolution of symptoms in survivors occurs in 1 to 24 weeks. Patients with NRTI-associated acidemia may recover more quickly after the use of cofactors such as thiamine, riboflavin, L-carnitine, vitamin C, and antioxidants.^{33,61} The indications for the use of these xenobiotics are unclear at this time; however, because of the relative lack of toxicity, they may be considered.

Chronic effects. Development of acidemia is more commonly associated with therapeutic use of reverse transcriptase inhibitors than with acute overdose. The mechanism is likely identical to that described above. Other common adverse

effects are somewhat agent specific and include hematologic toxicity after zidovudine, pancreatitis with didanosine, hypersensitivity after abacavir, and sensory peripheral neuropathy after stavudine and didanosine.^{60,61,89,128,153}

Nonnucleoside Reverse Transcriptase Inhibitors. The nonnucleoside reverse transcriptase inhibitors bind directly to reverse transcriptase enzymes enabling allosteric inhibition of enzymatic function.²³² Delavirdine (Rescriptor), efavirenz (Sustiva), etravirine (Intelence), nevirapine (Viramune), and rilpivirine (Endurant) comprise the currently available xenobiotics.

There are a paucity of acute overdose data on these xenobiotics, although they generally appear to have limited toxicity. An adult male with a reported ingestion of 6 g of nevirapine had a sustained laboratory elevation in γ -glutamyl transferase, but no other reported effects.⁷¹ An infant received a 40 times therapeutic dose of nevirapine with mild neutropenia and metabolic acidosis with elevated lactate concentration.³⁰ Finally, a 12 year-old child reported an ingestion of 3 g of efavirenz resulting in throat burning, visual impairment, peripheral nervous system abnormalities, and nightmares.¹⁶⁰ Treatment should include supportive care until more information is available. The nonnucleoside reverse transcriptase inhibitors are also limited in toxicity after chronic use. Use of nevirapine and delavirdine commonly results in hypersensitivity reactions such as rash. Efavirenz is reported to result in dizziness and dysphoria. Otherwise, toxicity can result from the ability of these xenobiotics to either inhibit or enhance CYP isozymes in the metabolism of other xenobiotics.

Protease Inhibitors. Protease inhibitors inhibit the vital enzyme (proteinase), which is required for viral replication.⁷⁸ Currently available xenobiotics include atazanavir (Reyataz), darunavir (Prezista), fosamprenavir (Lexiva), indinavir (Crixivan), nelfinavir (Viracept), ritonavir (Norvir), saquinavir mesylate (Invirase), and tipranavir (Aptivus).

Data after protease inhibitor overdose are limited. A review of data submitted to the manufacturer of indinavir found that of 79 reports, the complaints were nausea, vomiting, abdominal pain, and nephrolithiasis. Protease inhibitors as a class commonly result in gastrointestinal symptoms and rash.⁷⁸ Drug interactions can occur due to inhibition of CYP isoenzymes.¹⁷⁰ A unique finding is an altered fat distribution pattern that, over time, results in lymphodystrophy central obesity, “buffalo hump,” breast enlargement, cushingoid appearance, and peripheral wasting.⁷⁸

Fusion Inhibitors. This class of xenobiotics interferes with the binding or entry of the HIV virion into the cell.²³ No acute overdose data are available for this class, but after chronic use, hypersensitivity, hepatotoxicity, and infusion reactions seem to be of greatest concern.^{16,156,163} The currently available drugs include enfuvirtide (Fuzeon) and maraviroc (Selzentry).

Integrase Inhibitor. This class of xenobiotics prevents the activity of the enzyme in HIV to function normally. This enzyme is responsible for the incorporation of the virus into DNA. The currently available xenobiotic is raltegravir (Isentress), although elvitegravir and dolutegravir are in stage 2 and 3 clinical trials, respectively. No information is currently available regarding its toxicity after acute overdose. It appears that these xenobiotics are well tolerated at therapeutic doses with a potential association with myotoxicity.

C-C Chemokine Receptor Type 5 Antagonists. This class of xenobiotics antagonize the receptor by which HIV enters cells. Maraviroc (Selzentry) is the only C-C chemokine receptor type 5 inhibitor currently available. No information is currently available regarding its toxicity after acute overdose.

SUMMARY

- Adverse effects attributable to antimicrobials are largely related to chronic administration, although, rarely, acute toxicity does occur after large exposures.
- Acute toxic effects of antimicrobials are far more common following intravenous administration, xenobiotic interactions, or after iatrogenic overdose.
- Vigilance on the part of the health care professional will prevent the majority of acute toxic manifestations following antimicrobial use.

58 ANTITUBERCULOUS MEDICATIONS

Christina H. Hernon

HISTORY AND EPIDEMIOLOGY

Approximately one-third of the total population of the world, or 2 billion people, are infected with *Mycobacterium tuberculosis*. An estimated 8.8 million new cases of disease are diagnosed, and 1.6 million persons die from tuberculosis (TB) annually.³ In 2011, the incidence of TB in the United States was the lowest recorded (10,521 new cases) since the inception of national reporting in 1953.²² The introduction of isoniazid (INH) into clinical practice in 1952 produced a steady decline in the number of TB cases in the United States over the subsequent 30 years. However, between 1985 and 1991, there was a resurgence in TB cases in the United States resulting primarily from the effects of human immunodeficiency virus (HIV), homelessness, deterioration in the health care infrastructure, and an increase in immigration. With the initiation and implementation of containment strategies, the spread of the infection slowed by aggressive case identification and patient-centered management, including directly observed therapy, social support, housing, and substance abuse treatment. These methods have decreased the prevalence rate in the United States as well as worldwide. In 2005, the TB incidence was stable or declining worldwide, although the total number of new TB cases continued to increase slowly. Also in that year, extensively drug-resistant tuberculosis (XDR-TB) was recognized.^{7,21,94} In 2010, at least 5% to 10% of multidrug-resistant tuberculosis (MDR-TB) strains were extensively drug-resistant to both INH and rifampin, all fluoroquinolones, and at least one of three injectable drugs (capreomycin, kanamycin, and amikacin).¹³³ At present, populations that remain at risk for TB include HIV-positive patients, homeless people, people with alcoholism, injection drug users, health care workers, prisoners, prison workers, and Native Americans. In addition, the TB rate in foreign born persons is nearly 10 times higher than in US born persons. In the US population, countries of birth generating the highest number of TB cases are Mexico, the Philippines, India, and Vietnam.^{7,21} The use of second-line (reserve) drugs and multidrug antituberculous regimens for MDR-TB and XDR-TB resulted in an incidence of adverse drug effects increasing to 40% to 70% and sometimes requiring discontinuation of the treatment. Hepatotoxicity, peripheral neuropathy, and ocular neuropathy are often irreversible and potentially fatal.

ISONIAZID

Pharmacology

Isoniazid (INH, or isonicotinic hydrazide) is structurally related to nicotinic acid (niacin, or vitamin B₃), nicotinamide adenosine dinucleotide (NAD), and pyridoxine (vitamin B₆) (Fig. 58–1). The pyridine ring is essential for antituberculous activity. INH itself does not have direct antibacterial activity. It is a prodrug that undergoes metabolic activation by KatG, a catalase peroxidase in *M. tuberculosis* that produces a highly reactive intermediate,^{95,135} which in turn interacts with InhA, a mycobacterial enzyme that functions as an enoyl-acyl carrier protein (enoyl-ACP) reductase.^{92,93} InhA is required for the synthesis of very-long-chain lipids, mycolic acids (containing between 40 and 60 carbons) that are important components of mycobacterial cell walls.

FIGURE 58–1. Isoniazid and related compounds.

The activated form of INH is stabilized by the pyridine ring. Enoyl-ACP reductase (InhA) catalyzes the NADH-

dependent reduction of the double bonds in the growing fatty acid chain linked to acyl carrier proteins. This INH metabolite enters the binding site of InhA, where it reacts with the reduced form of nicotinamide adenine dinucleotide (NADH).⁹⁵ The covalently linked INH-NADH complex remains bound to the active site of InhA, irreversibly inhibiting the enzyme.^{76,92}

Pharmacokinetics

When therapeutic doses of 300 mg are administered orally, INH is rapidly absorbed, reaching peak serum concentrations typically within 2 hours.^{60,88,89} INH diffuses into all body fluids with a volume of distribution of approximately 0.6 L/kg and has negligible binding to serum proteins. After the drug penetrates infected tissue, it persists in concentrations well above those generally required for bactericidal activity.⁸⁹

The primary metabolic pathway for INH is via N-acetylation via hepatic acylamine N-acetyltransferase type 2 (NAT2) to acetylisoniazid, which may be (1) excreted by the kidney; (2) oxidized to hydroxylamine, a hepatotoxic metabolite via CYP2E1¹³⁰; (3) directly hydrolyzed to hepatotoxic hydrazine; or (4) further metabolized by NAT2 to (somewhat hepatotoxic) acetylhydrazine, which may be further metabolized by NAT2 to nontoxic diacetylhydrazine. Hydrazine and (to a lesser extent) acetylhydrazine are oxidized by CYP2E1 to reactive metabolites, which induce oxidative stress or alter lipid metabolism, resulting in hepatic apoptosis or steatosis. The mechanisms and circumstances of hepatotoxicity are not clearly elucidated and are of continuing interest in research.¹³⁰ Approximately 75% to 95% of INH is renally eliminated in the form of these hepatic metabolites within 24 hours of administration.⁴⁹ N-acetyltransferase-2 (NAT2) exhibits Michaelis-Menten kinetics but is genotypically polymorphic, and the activity of an individual's enzymes is determined by an autosomal dominant inheritance pattern, with homozygous fast acetylators (FF), heterozygous fast acetylators (FS), and homozygous slow acetylators (SS). Patients are distinguishable phenotypically as fast, intermediate, and slow acetylators. Whereas the fast acetylation isoform is found in 40% to 50% of American whites and African Americans, the fast acetylator isoenzymes are found in 80% to 90% of Asians and Inuits.³⁷ These isoforms are distinguishable by the following characteristics: (1) slow acetylators have less presystemic clearance, or first-pass effect, than do fast acetylators; (2) fast acetylators metabolize INH five to six times faster than slow acetylators; and (3) serum INH concentrations are 30% to 50% lower in fast acetylators than in slow acetylators. The elimination half-life of INH is approximately 70 minutes in fast acetylators, and 180 minutes in slow acetylators. Twenty-seven percent of INH is excreted unchanged in urine by slow acetylators compared with 11% excretion in fast acetylators. Slow acetylators are at increased risk of peripheral neuropathy and may require dose adjustments.¹¹⁷ The clearance of INH averages 46 mL/min.^{10,125} Additionally, a small portion of INH is directly hydrolyzed into isonicotinic acid and hydrazine, and this pathway is of greater quantitative significance in slow acetylators than in rapid acetylators. Although both hepatic microsomal oxidation by CYP2E1 of hydrazine or the acetylhydrazine intermediate into reactive intermediates have been proposed as causes of INH related hepatotoxicity, there is no significant association between variations in genetic polymorphisms and hepatotoxicity.^{44,81,121,130} There is increasing evidence that hydrazine is linked to direct hepatotoxicity as well as causing hepatotoxicity via an immune mediated, idiosyncratic mechanism.⁷⁷ **Figure 58–2** illustrates the metabolism of INH.

FIGURE 58–3. The effect of isoniazid on γ -aminobutyric acid (GABA) synthesis.

Pyridoxine is converted in vivo to an active form, pyridoxal-5'-phosphate, which serves as an important cofactor in many biotransformation reactions such as transamination, transketolation, and decarboxylation. INH metabolites inhibit the enzyme pyridoxine phosphokinase, which converts pyridoxine (vitamin B₆) to its active form, pyridoxal-5'-phosphate, which is a required cofactor for many pyridoxine dependent enzyme systems in the body, including two enzymes that control GABA metabolism.^{25,59,79} Glutamic acid decarboxylase (GAD) catalyzes GABA synthesis from glutamate, and GABA aminotransferase degrades the inhibitory neurotransmitter. The inhibitory effects are greater on GAD, which leads to both decreased GABA and elevated glutamate concentrations.¹²⁷

Pyridoxine depletion is also involved in a decrease in catecholamine synthesis and interferes with the synthesis of and/or reacts with NAD to form inactive hydrazone adducts, thereby disrupting cellular reduction/oxidation reactions.

Pyridoxine depletion is further compounded when INH directly reacts with pyridoxal phosphate to produce an inactive hydrazone complex that is renally excreted and thereby increases renal losses of this required cofactor.^{79,125} Urinary excretion of pyridoxine and its metabolites increases with increasing INH dose, reflecting the effect of INH on pyridoxine metabolism.

Structurally similar chemicals exert similar acute toxic effects. Monomethylhydrazine, a metabolite produced from gyromitrin isolated from the *Gyromitra* spp (“false morel”) mushroom, and the hydrazines used in liquid rocket fuel have a similar mechanism of action (Chap. 120).

Interactions with Other Drugs and Foods

Drug–drug interactions associated with INH are mediated through alteration of hepatic metabolism of several CYP enzymes. The majority of these interactions are inhibitory, with decreased CYP-mediated transformations, particularly demethylation, oxidation, and hydroxylation (Chap. 13). Clinically relevant adverse effects with elevated concentrations of theophylline (CYP1A2), phenytoin (CYP2C9/CYP2C19), warfarin (CYP2C9/CYP2C19), valproic acid, and carbamazepine (CYP3A4) are caused by decreased hepatic metabolism of these xenobiotics.^{33,106,131} The CYP2E1 cytochrome subtype, however, exhibits a complex response to INH; a therapeutic dose of INH induces expression of CYP2E1, but simultaneously binds, stabilizes, and inhibits its metabolic activity. Eventual dissociation of INH from the enzyme active site creates an increased intracellular concentration of CYP2E1 available to metabolize potential substrates. The formation of the acetaminophen (APAP) metabolite responsible for toxicity, NAPQI (N-acetyl-p-benzoquinoneimine), is catalyzed by CYP2E1. INH mediated effects in APAP-induced hepatotoxicity are uncertain because of differences in acetylator status (fast, slow) and variations in CYP2E1 activity.^{24,106}

INH interacts with numerous foods. INH is a weak monoamine oxidase inhibitor; both tyramine reactions to foods (aged cheeses, wines) and serotonin toxicity from meperidine are reported in patients taking INH. Clinical effects include flushing, tachycardia, and hypertension.^{32,43,69,113} Furthermore, INH inhibits the enzyme histaminase, leading to exacerbated reactions after the ingestion of histamine in scombrototoxic fish.^{55,79,106} Table 58–1 summarizes additional INH drug and food interactions.

TABLE 58–1. Adverse Reactions and Drug Interactions of Antituberculous Drugs

Drug	Major Adverse Reactions	Drug Interactions/Clinical Effect	Monitoring	Comments
Isoniazid (INH)	Acute: seizures, acidosis, coma, hyperthermia, oliguria, anuria Chronic: elevation of liver enzyme concentrations, autoimmune hepatitis, arthritis, anemia, hemolysis, eosinophilia, peripheral neuropathy, optic neuritis, vitamin B ₆ deficiency (pellagra)	Rifampin, PZA, ethanol: hepatic necrosis Acetaminophen: hepatic necrosis Warfarin: increased INR Theophylline: tachycardia, vomiting, seizures, acidosis Phenytoin: increased phenytoin concentrations Carbamazepine: altered mental status Meperidine: serotonin toxicity Lactose: decreased INH absorption Antacids: decreased INH absorption Red wine/soft cheese: tyramine reaction Fish (scombroid): flushing, pruritus	Liver enzymes, ANA, CBC	HIV enteropathy may decrease absorption; INH should not be given with lactose-containing drug formulations because lactose can form hydrazones and lower INH concentrations
Rifampin	Acute: diarrhea, periorbital edema Chronic: hepatitis, reddish discoloration of body fluids	Protease inhibitors: decreased serum concentration of protease inhibitor Delavirdine: increased HIV resistance Cyclosporine: graft rejection Warfarin: decreased INR Oral contraceptives: ineffective contraception Methadone: opioid withdrawal Phenytoin: higher frequency of seizures Theophylline: decreased theophylline concentrations Verapamil: decreased cardiovascular effect	If administered with HIV antiretrovirals, viral titers should be followed. Liver enzymes; monitor serum concentrations of drugs (ie, phenytoin, cyclosporine) or clinical markers of efficacy (ie, INR)	Interactions of rifampin with several HIV medications are very poorly described; changes in dosing or dosing interval for both rifampin and antiretroviral drugs may be required; teratogenic
Ethambutol	Chronic: optic neuritis, loss of red-green discrimination, loss of peripheral vision		Visual acuity, color discrimination	Contraindicated in children too young for formal ophthalmologic examination
Pyrazinamide (PZA)	Chronic: hepatitis, decreased urate excretion	INH: increased rates of hepatotoxicity (when extended courses or high dose pyrazinamide used)	Liver enzymes	Courses of therapy of ≤ 2 months are recommended
Cycloserine	Chronic: depression, paranoia, seizures, megaloblastic anemia	INH: increased frequency of seizures	CBC, psychiatric monitoring	
Ethionamide	Chronic: orthostatic hypotension, depression	Cycloserine: may increase CNS effects	Blood pressure, pulse, orthostasis	
para-Aminosalicylic acid	Chronic: malaise, GI upset, elevated liver enzyme concentrations, hypersensitivity reactions, thrombocytopenia		Liver enzymes, CBC	
Capreomycin	Chronic: hearing loss, tinnitus, proteinuria, sterile abscess at IM injection sites		Audiometry, kidney function tests	

ANA = antinuclear antibodies; CBC = complete blood count; CNS = central nervous system; HIV = human immunodeficiency virus.

Pregnancy

The use of INH in pregnancy is of concern because it is a class C drug, crosses the placenta, and produces umbilical cord serum concentrations comparable to maternal serum concentrations.^{13,14,61} Mammalian teratogen studies suggest that INH is not a human teratogen, although fetal deformities after acute overdose of INH are reported.^{70,125} Administration of INH to pregnant women was not associated with cancer in their offspring. Although INH readily enters breast milk, breastfeeding during therapy is considered acceptable.^{100,125}

Clinical Manifestations of Isoniazid Toxicity

Acute Toxicity. INH produces the triad of seizures refractory to conventional therapy, severe metabolic acidosis, and coma. These clinical manifestations may appear as soon as 30 minutes after ingestion.^{53,57,119} The case fatality rate of a single acute ingestion may be as high as 20%.^{15,18} Although vomiting, slurred speech, dizziness, and tachycardia may represent early manifestations of toxicity, seizures may be the initial sign of acute overdose.⁷² Seizures may occur after the ingestion of greater than 20 mg/kg of INH and invariably occur with ingestions greater than 35 to 40 mg/kg. Patients with underlying seizure disorders may develop seizures at lower doses.¹⁵ Hyperreflexia or hyporeflexia may herald INH induced seizures. Consciousness may return between seizures, or status epilepticus can occur.^{30,84} Because GABA, the primary inhibitory neurotransmitter, is depleted in acute INH toxicity, seizure activity may persist until GABA concentrations are restored even with anticonvulsant therapy.

Acute INH toxicity is often associated with seizures and an anion gap metabolic acidosis associated with a high serum lactate concentration. Typically, arterial pH ranges between 6.80 and 7.30, although survival in the setting of an arterial pH of 6.49 was reported.⁵³ Paralyzed animals poisoned with INH do not develop elevated lactate concentrations, a finding that suggests the lactate arises from intense muscular activity.^{25,85}

In acute severe INH toxicity, coma may last as long as 24 to 36 hours and persist beyond both the termination of seizures and the resolution of acidemia. The cause of coma is unknown.^{11,53} Additional sequelae from acute INH toxicity include rhabdomyolysis, kidney failure, hyperglycemia, glycosuria, ketonuria, hypotension, and hyperthermia.^{4,8,19,86,125,126}

Chronic Toxicity. Chronic therapeutic INH use is associated with a variety of adverse effects. Overall incidence of adverse reactions to INH is estimated to be 5.4%,⁴⁹ the most serious of which is hepatocellular necrosis.³⁹ Although asymptomatic elevation of aminotransferases is common in the first several months of treatment, laboratory testing may reveal the onset of hepatitis up to one year after starting INH therapy. In 1978, after several deaths among patients receiving INH therapy, the US Public Health Service reported the incidence of clinically evident hepatitis as 1% of those taking INH; of that subgroup, 10% died, for an overall mortality rate of 0.1%.^{17,66} Research performed since the resurgence of TB, however, identified a considerably lower rate of hepatotoxicity. Clinically manifest hepatitis occurred in only 11 patients in a population of 11,141 persons receiving INH and close monitoring, yielding an incidence of 0.1%.⁸³ Additional studies suggest that the death rate from INH hepatotoxicity is only 0.001% (two of 202,497 treated patients).⁹⁸ Hepatotoxicity is associated with chronic overdose, increasing age, comorbid conditions such as malnutrition, and combinations of antituberculous drugs that may serve as cytochrome inducers. Overt hepatic failure often occurs if INH therapy is continued after the onset of hepatocellular injury in both adults and children.^{35,36,50,74,110,129} The incidence of hepatitis is two to four times higher in pregnant women than in nonpregnant women.⁴¹

Isoniazid induced hepatitis can arise via two pathways.^{35,132} The first involves an immunologic mechanism resulting in hepatic injury that is thought to be idiopathic.^{103,125} The association of hepatitis with lupus erythematosus, hemolytic anemia, thrombocytopenia, arthritis, vasculitis, and polyserositis supports an immunologic process.^{102,125} However, symptoms commonly found in autoimmune disorders such as fever, rash, and eosinophilia are usually absent with drug induced lupus erythematosus, and rechallenge with INH often fails to provoke recurrence of hepatocellular injury.^{35,102,132} The second, more common mechanism involves direct hepatic injury by INH or its metabolites. The metabolites believed responsible for hepatic injury are acetylhydrazine and hydrazine (Fig. 58–2).^{44,81,120}

Peripheral neuropathy and optic neuritis are known adverse drug effects of chronic INH use. Neurotoxicity is probably caused by pyridoxine deficiency aggravated by the formation of pyridoxine-INH hydrazones.³⁷ Peripheral neuropathy, the most common complication of INH therapy, presents in a stocking-glove distribution that progresses proximally. Although primarily sensory in nature, myalgias and weakness may occur.¹¹¹ Peripheral neuropathy is generally observed in severely malnourished, alcoholic, uremic, or diabetic patients; it is also associated with slow acetylator status, an effect that leads to increased INH concentrations and, consequently, increased pyridoxine depletion.⁴⁶ Optic neuritis may occur with INH therapy, usually concurrent with other medications such as ethambutol or etanercept, and presents as decreased visual acuity, eye pain, and dyschromatopsia; visual field testing may reveal central scotomata and bitemporal hemianopsia.^{47,57,64} INH is also associated with such findings of CNS toxicity as ataxia, psychosis, hallucinations, and coma.^{1,9,45,97}

Diagnostic Testing

Acute INH toxicity is a clinical diagnosis that may be inferred by history and confirmed by measuring serum INH concentrations.¹⁰⁵ Acute toxicity from INH is defined as a serum INH concentration greater than 10 mg/L one hour after ingestion, greater than 3.2 mg/L 2 hours after ingestion, or greater than 0.2 mg/L six hours after the ingestion.⁸⁴ Because serum INH concentration measurements are not widely available, clinicians cannot rely on serum concentrations to confirm the diagnosis or initiate therapy. Because of the risk of hepatitis associated with chronic INH use, hepatic aminotransferases should be regularly monitored after therapy is started. In critically ill patients, serum should be assessed for acidemia, kidney function, creatine phosphokinase (CPK), and urine myoglobin indicating rhabdomyolysis and possible kidney failure.

Management

Acute Toxicity. The antidote for INH induced neurologic dysfunction is pyridoxine (Antidotes in Depth: A14). Pyridoxine rapidly terminates seizures, corrects metabolic acidosis, and reverses coma. The efficacy of pyridoxine is correlated with the administered dose; one study identified recurrent seizures in 60% of patients who received no pyridoxine and in 47% of those who received 10% of the ideal pyridoxine dose, and no seizures in patients who received the full dose of pyridoxine.¹²⁴ To treat acute toxicity, the pyridoxine dose in grams should equal the amount of INH ingested in grams, with a first dose of up to 5 g intravenously in adults. Unknown quantities of ingested INH warrant initial empiric treatment with a pyridoxine dose of no more than 5 g (pediatric dose, 70 mg/kg to a maximum of 5 g). Pyridoxine should be administered at a rate of 1 g every 2 to 3 minutes. Seizures that persist beyond administration of the initial dose should receive an additional similar dose of pyridoxine.⁶

Hospital pharmacies may stock insufficient quantities of intravenous (IV) pyridoxine to treat even a single patient with a large INH ingestion.¹⁰¹ In the event that IV formulations are unavailable in sufficient quantities, pyridoxine tablets may be crushed and administered with fluids via a nasogastric tube.¹⁰¹

Conventional anticonvulsants, although generally used as first line therapy, demonstrate variable effectiveness in terminating INH induced seizures. Benzodiazepines may be used to potentiate the antidotal efficacy of pyridoxine, particularly if optimal doses of the antidote are unavailable. The benzodiazepines act synergistically with pyridoxine, as well as possessing inherent GABA agonist activity, but they may be ineffective as the sole treatment of acute INH poisoning because of their reliance on GABA to exert their activity.^{26,27,57,124} Phenytoin has no intrinsic GABAergic effect and is not recommended as therapy for patients with INH-induced seizures.^{57,84,96} Barbiturates that have potent GABA agonist activity are expected to be as effective as the benzodiazepines, although the risk of respiratory depression is greater with this class of anticonvulsant. The efficacy of propofol in terminating INH induced seizures has not been evaluated in humans.

Although hemodialysis has been used to enhance elimination of INH in acute overdose, with clearance rates reported as high as 120 mL/min, hemodialysis is rarely indicated for initial management unless associated with kidney failure.^{19,125}

Asymptomatic patients who present to the emergency department within 2 hours of ingestion of toxic amounts of INH should receive prophylactic administration of 5 g of oral or IV pyridoxine. This recommendation is based on the observation that INH reaches its peak serum concentration within 2 hours of ingestion of therapeutic doses. Asymptomatic patients may be observed for a 6 hour period for signs of toxicity. Acute toxicity is unlikely to manifest more than 6 hours beyond ingestion.

Gastrointestinal (GI) decontamination should be performed by administering activated charcoal only in patients who are awake and able to comply with therapy.¹⁰⁹ Late GI decontamination with activated charcoal will probably be ineffective in preventing toxicity because delayed absorption has not been observed.¹⁰⁴ Orogastric lavage is relatively contraindicated unless the patient is intubated because of the risk of seizures.

Chronic Toxicity. Hepatitis (defined as aminotransferase concentrations more than two to three times baseline) resulting from therapeutic INH administration mandates termination of therapy; malnourished patients may require nutritional support. After resolution of liver injury, INH may be restarted, provided aminotransferase concentrations are closely monitored, with reassessment in six weeks or any time the patient experiences nausea, vomiting, or abdominal discomfort.^{35,110} Pyridoxine does not reverse hepatic injury; consequently, surveillance for and recognition of hepatocellular injury remains essential. Cases of hepatitis refractory to medical therapy may require liver transplantation.^{38,54,129}

Isoniazid produces an axonopathy caused by pyridoxine depletion and manifests as peripheral neuropathies, cerebellar findings, and psychosis. Neurotoxicity is commonly treated with as much as 50 mg/d of oral pyridoxine, although doses as low as 6 mg/d appear to be effective.^{1,9,97,114} Because of its effectiveness in preventing neurologic toxicity, pyridoxine is often used concurrently with INH therapy.

RIFAMYCINS

Pharmacology

Rifamycins are a class of macrocyclic antibiotics derived from *Ammycolatopsis mediterranei*. Xenobiotics in this class include rifampin (a semisynthetic derivative), rifabutin, and rifapentine, of which the first two are most commonly used.⁴⁹ Rifampin inhibits the initial steps in RNA chain polymerization through the formation of a stable drug enzyme complex with RNA polymerase. Disruption of RNA synthesis interrupts protein synthesis, leading to cell death. Whereas mycobacterial RNA polymerase is susceptible to rifampin, eukaryotic RNA polymerase is not. High concentrations of rifamycin antibiotics, however, can affect mammalian mitochondrial RNA synthesis, as well as reverse transcriptases and viral DNA dependent RNA polymerases.⁴⁹

Pharmacokinetics and Toxicokinetics

When administered orally, rifampin reaches peak serum concentrations in 0.25 to 4 hours; foods, but not antacids, interfere with absorption.⁸⁹ Rifampin is secreted into the bile and undergoes enterohepatic recirculation. Although the recirculating antibiotic is deacetylated, the metabolite retains antimicrobial activity. The half-life of rifampin, which is normally 1.5 to 5 hours, increases in the setting of hepatic dysfunction. After therapy is started, however, rifampin autoinduces its metabolism to shorten its half-life by approximately 40%. Rifampin is distributed widely into body compartments, and imparts a reddish color to all body fluids, including the cerebrospinal fluid⁴⁹ and in this setting has been erroneously identified as xanthochromia suggesting subarachnoid hemorrhage to the clinician.⁵⁷ Because mycobacteria rapidly develop resistance to rifampin, it should not be used as the sole therapy against TB.⁴⁹

In large overdose, elimination half-life has been observed within the normal range expected after therapeutic dosing. Rifampin may inhibit hepatic excretion of bilirubin, causing transient elevations; however, this may also be caused by interference with the bilirubin assay because of the reddish color imparted to all body fluids, including serum.¹²⁸ Rifampin therapy carries greater teratogenic risk than other antituberculous therapies, with 4.4% incidence of malformation. Anencephaly, hydrocephalus, and congenital limb abnormality and dislocations are reported.^{14,116} Rifampin is associated with hemorrhagic disease of the newborn¹⁴ but is nevertheless compatible with breastfeeding because only minute amounts of rifampin are secreted into breast milk.^{14,115}

Drug–Drug Interactions

Rifamycins are potent inducers of CYP enzymes, which result in numerous drug interactions ([Chap. 13](#)). Of the rifamycins, rifampin has greater activity in inducing CYP3A4 than rifapentine; rifabutin has the least inductive activity of the class.⁷¹ Rifampin also induces CYP1A2, CYP2C9, and CYP2C19.¹³¹ Additionally, the ability of rifampin to induce CYP3A4 is strongly correlated with p-glycoprotein (P-gp) concentrations. P-gp is a transmembrane protein that functions as a cellular efflux pump of endogenous and exogenous xenobiotics; variations in expression of P-gp significantly affects the bioavailability of many xenobiotics and subsequent drug–drug interactions ([Chaps. 9 and 13](#)).⁴⁰ Concurrent administration of rifampin thus affects the metabolism of an array of drugs such as warfarin, cyclosporine, phenytoin, opioids, and oral contraceptives.^{40,108,131} P-gp induction by rifampin therefore may be responsible for a variety of pathophysiologic processes, including insufficient anticoagulation in patients receiving oral anticoagulants, acute graft rejection in transplant patients, graft-versus-host disease, difficulty controlling phenytoin concentrations, methadone withdrawal, and unplanned pregnancy. Effects arising from CYP3A4 induction begin within 5 to 6 days after rifampin is started and persist for up to 7 days after therapy is stopped.⁴⁹

Rifamycins and HIV

Coinfection with both TB and HIV is common, causing approximately 4 million deaths per year worldwide. Approximately one-third of all patients with HIV also have TB, and concurrent highly active antiretroviral therapy (HAART) and antituberculous therapy decrease mortality.¹²³ However, many factors influence the efficacy and feasibility of treating these illnesses. There is decreased absorption of nearly all antituberculous drugs in patients with advanced HIV caused by chronic diarrhea, intestinal pathogens, and general malabsorption. Also, there are many drug–drug interactions between antituberculous and HIV medications caused by alterations in absorption, cytochrome enzymes, P-gp transporters, and noncytochrome metabolism.^{40,51,58,121} This often creates additive toxicities that compromise efficacy as well as compliance. This is particularly true when combining rifamycins and HIV medications. Toxic manifestations of individual xenobiotics may be additive, such as combining nevirapine and rifampin, which both have risk of skin rash and hepatitis. Caution should be exercised when combining these therapies, and individual toxicities should be reviewed to avoid summative effects. [Table 58–1](#) lists common adverse effects and drug–drug interactions.

Clinical Manifestations

Acute Toxicity. The most common side effects of acute rifampin overdose are GI in nature consisting of epigastric pain, nausea, vomiting, and diarrhea.^{35,49} The presence of diarrhea distinguishes rifampin ingestion from overdose of other antituberculous medications. Three reported deaths are described from rifampin or rifampicin ingestion; an autopsy performed on one of these patients demonstrated the presence of pulmonary edema, although no causation was implied.^{12,62,91} Other effects include flushing, angioedema, and obtundation. Overdoses of rifampin in children can result in facial or periorbital edema. Anterior uveitis is occasionally observed, as are neurologic effects consisting of generalized numbness, extremity pain, ataxia, and muscular weakness.⁴⁸ Isolated rifamycin overdose infrequently produces serious acute effects.

Chronic Toxicity. When rifampin was originally introduced as an antituberculous medication, hepatitis was more frequently observed in patients taking combination therapy with INH than in those taking INH alone. These findings potentially arise from the ability of rifampin to induce cytochromes responsible for INH hepatotoxicity and not from direct hepatic injury by rifampin itself. Liver injury, when attributable to rifampin alone, is predominantly cholestatic, suggesting that clinical surveillance for hepatic injury is important as is regular biochemical monitoring.^{35,87} Rifampin alters the metabolism of other xenobiotics, such as INH, pyrazinamide (PZA), and APAP, to increase their potential for hepatotoxicity.^{35,82} Although some reports highlight increased compliance and typically mild and transient hepatotoxicity with combined rifampin and PZA treatment for latent TB infection, other recent studies suggest a significant risk of fatal hepatotoxicity, and the Centers for Disease Control and Prevention recommends generally avoiding this combination of drugs.⁷⁵

A condition similar to a viral syndrome may result from a hypersensitivity reaction that is associated with rifampin therapy. The syndrome, which occurs in 20% of patients receiving high doses or intermittent (less than twice weekly) dosing, includes fever, chills, and myalgias. Eosinophilia, hemolytic anemia, thrombocytopenia, and interstitial nephritis can develop in severe cases, and acute kidney injury is likely related to hypersensitivity. Acute kidney injury is rarely oliguric and is usually self-limited; patients usually recover with supportive care, although rechallenge with rifampin should be undertaken only with caution.⁸⁷

The concomitant administration of rifampin and protease inhibitors results in increased rates of arthralgias, uveitis, leukopenia, and skin discoloration. Identical side effects occurred during the simultaneous administration of rifampin and CYP3A4 inhibitors such as clarithromycin, suggesting that toxic effects arise from elevated serum rifampin concentrations.¹⁶ Current recommendations are that rifampin not be given with protease inhibitors, except for ritonavir in rare circumstances. In patients already taking protease inhibitors, rifabutin may be used in place of rifampin.⁹⁰

Diagnostic Testing and Management

Management of patients with acute rifampin overdose is primarily observational and proactive. Stabilization of vital signs and administration of activated charcoal are usually adequate, although clinicians should remain vigilant for coingestants. For chronic toxicity, recognition of interactions between rifampin and other xenobiotics is critical. Hepatic function should be monitored because of the ability of rifampin to augment the hepatotoxicity of other xenobiotics. Treatment for hepatic injury involves withholding rifampin therapy and reassessing the appropriateness of other xenobiotics administered to the patient. Supportive care for hepatotoxicity may be required. Influenza-like symptoms and acute kidney injury secondary to rifampin may respond to decreasing the interval between administration of the medication.⁸⁷ Although rifampin interacts with protease inhibitors, the utility of therapeutic drug monitoring is uncertain because the correlation of clinical events with serum concentrations of rifampin and antiretroviral drugs is unknown.¹⁶

ETHAMBUTOL

Pharmacology

Ethambutol is effective against *M. tuberculosis* and *Mycobacterium kansasii* as well as some strains of *Mycobacterium avium* complex; however, it has no effect on other bacteria. Ethambutol inhibits arabinosyl transferases, interfering with biosynthesis of arabinogalactan and liparabinomannan, which are required for polymerization of arabinan within mycobacterial cell walls.^{49,63}

Pharmacokinetics

Only the D(+) isomer is used therapeutically because the L(–) isomer is the major contributor to optic neuritis, but both enantiomers are bactericidal.¹⁰⁷ It is taken up rapidly by growing cells, where bacteriostatic effects appear approximately 24 hours after ethambutol is incorporated by mycobacteria.⁴⁹ About 80% of an oral dose is absorbed, but both foods and antacids decrease absorption.^{16,49} Maximum serum concentrations are reached within 4 hours of oral administration and are proportional to the dose. Ethambutol is approximately 20% to 30% protein bound and has a half-life of 4 to 6 hours.^{49,68} Three-fourths of a standard dose is excreted unchanged in the urine by a combination of glomerular filtration and tubular secretion. Consequently, ethambutol accumulates in patients with impaired glomerular filtration rate (GFR), making adjustments in dosing necessary.⁴⁹ Increasingly, mutations in the *Mycobacterium embB* gene confer resistance to ethambutol, as high as 14.2%, with acquired resistance reaching nearly 40%.⁶³

Ethambutol is considered safe for use during pregnancy as a first-line medication. Although a 2.2% incidence of congenital abnormalities was identified in women undergoing ethambutol therapy, no consistent pattern of abnormalities occurred in their offspring.¹⁴ Although ethambutol is excreted into breast milk in approximately a 1:1 ratio with serum, it is considered to be compatible with breastfeeding.¹⁴

Clinical Manifestations and Management

Acute overdose of ethambutol is generally well tolerated, although a death has been reported.⁶² More commonly, nausea, abdominal pain, confusion, visual hallucinations, and optic neuropathy occur after acute ingestions of greater than 10 g.³⁴ Although stabilization of vital signs and GI decontamination with activated charcoal remain the hallmarks of therapy, clinicians must remain vigilant for coingestants, particularly INH. Hemodialysis is rarely used as treatment for multidrug ingestions including ethambutol.³⁴

Although peripheral neuropathy and cutaneous reactions occur with chronic therapy, the most significant effect of the therapeutic use of ethambutol is unilateral or bilateral ocular toxicity presenting as painless blurring of vision, decreased perception of color, and loss of peripheral vision. These effects are largely dose and duration related and are typically reversible with drug discontinuation.^{23,29,122} Optic neuritis develops in approximately 15% of patients receiving 50 mg/kg/d, 5% of patients receiving 25 mg/kg/d, and fewer than 1% of those receiving 15 mg/kg/d.⁸⁷ Patients may develop subclinical ocular disease within 30 days of starting ethambutol.¹³⁴ The loss of peripheral vision and color discrimination that accompanies the optic neuropathy caused by ethambutol distinguishes this condition from the optic neuropathy secondary to INH.^{57,87}

Management of chronic toxicity from ethambutol involves cessation of therapy, although improvement may be hastened by treatment with hydroxocobalamin.^{49,57} Recovery is less likely in older patients and is related to the degree of visual impairment.¹²⁰

Ethambutol is a strong metal chelator, and inactivation of zinc and copper may be related to its induction of retinal cell vacuoles and enlarged lysosomes, which interfere with membrane permeability, possibly causing abnormal cell function and cell death.^{29,65} The visual abnormalities induced by ethambutol are similar to those caused by a hereditary condition known as Leber optic neuropathy. Both ethambutol and Leber hereditary optic neuropathy can affect oxidative phosphorylation through impairment of mitochondrial function.^{28,65} Ethambutol is suspected of mimicking this condition by binding intracellular copper, altering mitochondrial function, and producing neuronal injury.^{56,65} Alternatively, optic

neuritis may be related to zinc metabolism. Ethambutol chelates intracellular zinc to induce reversible vacuolar degeneration in retinal cultures. Progressive degeneration leads to irreversible neuronal destruction.²⁹ The effect of this injury is a shift in the threshold for wavelength discrimination without changing the absolute sensitivity of the cone system, which leads to a loss of red–green discrimination.¹¹²

Diagnostic Testing and Management

All patients should receive neuroophthalmic testing before ethambutol therapy. The use of visual evoked potentials is especially useful in identifying subclinical optic nerve disease. Furthermore, patients should receive regular visual acuity examinations, and clinicians should encourage patients to report any subjective visual symptoms. The use of ethambutol may be relatively contraindicated in children who are unable to comply with an ophthalmic examination.^{57,87}

PYRAZINAMIDE

Pharmacology and Pharmacokinetics

Pyrazinamide is a structural analog of nicotinamide with a mechanism of action similar to that of INH. Similar to INH, PZA is a prodrug. PZA requires deamidation to anionic pyrazinoic acid by pyrazinamidase, an endogenous cytoplasmic bacterial enzyme. In this form, PZA has no antibacterial activity, but after being exposed to acidic conditions, it becomes protonated to the uncharged, active form, 5-hydroxypyrazinoic acid, which enters the cell, accumulates, and kills the bacteria by disruption of mycolic acid biosynthesis. PZA is effective against both active and dormant bacteria, and its use in antituberculous regimens shortens the course of therapy; however, resistance rapidly develops if it is used as single-agent therapy, and it should therefore only be used with other antituberculous medications.⁴⁹ PZA is synergistic with rifampin and has greatest efficacy if administered during the first 2 months of treatment with both INH and rifampin; this regimen effectively shortens the treatment course to only 6 months.¹³⁶ After oral administration, PZA is rapidly absorbed, with maximum concentrations occurring within 1 to 2 hours of administration, and a half-life of approximately 9 hours. Hepatic metabolism to pyrazinoic acid and 5-hydroxypyrazinoic acid occurs with the metabolites subsequently renally excreted.⁴⁹

When introduced in the 1950s, PZA was administered in doses of 40 to 50 mg/kg for extended periods of time. The dosages produced clinical hepatitis, with manifestations of highly elevated aminotransferase and bilirubin concentrations. Of patients taking high-dose PZA, elevations in aminotransferases were identified in 20%, and symptomatic hepatitis was identified in 10%, with a small number of those who developed hepatitis dying from a fulminant hepatic failure. As a result of these findings, PZA was believed to be highly hepatotoxic, and its use was discouraged. The resurgence of multidrug-resistant mycobacteria, however, has forced clinicians to reassess the role of PZA. Modern dosing regimens of 30 mg/kg for brief courses of 2 months infrequently produce hepatic injury, with some studies suggesting that addition of PZA to multidrug TB regimens confers no additional risk for hepatotoxicity.³⁵

Pyrazinamide is rarely used in pregnancy because the risk of birth defects is poorly defined. Animal studies suggest that PZA has no teratogenicity at therapeutic doses.² PZA is minimally excreted into breast milk and is presumed safe for breastfeeding.¹⁴ It is considered a category C drug in pregnancy.

Diagnostic Testing

Proper dosing of PZA and short courses of therapy are the two most important factors in preventing toxicity. Treatment for hepatotoxicity involves cessation of PZA therapy in conjunction with supportive care.³⁵ PZA inhibits the renal excretion of uric acid, and hyperuricemia is observed. More than 90% of children treated with short courses developed elevated uric acid concentrations.⁹⁹ Most patients, regardless of age, remain asymptomatic and do not develop symptoms of gout. Toxic effects from acute overdose of PZA have not been reported.

CYCLOSERINE

Cycloserine, previously avoided because of its adverse effects, is being used increasingly as second-line treatment with other tuberculostatic medications when treatment with primary agents (INH, rifampin, ethambutol, and streptomycin) fails or as initial therapy when drug susceptibility testing indicates either MDR-TB or XDR-TB. Cycloserine is a structural

analog of alanine and demonstrates inhibition of D-alanine racemase and D-alanine ligase, which are involved in peptidoglycan cell wall synthesis.⁵² After oral doses, 70% to 90% of the drug is absorbed, and peak concentrations are reached in 3 to 8 hours. Cycloserine is distributed throughout all tissues and body fluids and easily crosses the blood–brain barrier. Less than 35% of the antibiotic is metabolized, and remaining xenobiotic is excreted unchanged in the urine.^{31,49}

Toxicity is dose dependent and occurs in as many as 50% of patients taking cycloserine. Cycloserine is a partial agonist at the NMDA/glycine receptor, which may contribute to neurologic effects such as somnolence, headache, tremor, dysarthria, vertigo, confusion, irritability, and seizures.⁵² Psychiatric manifestations include paranoid reactions, depression, and suicidal ideation. Reversible hypersomnolence and asterixis are reported with cycloserine, suggesting reversible thalamic neurotoxicity, which is corroborated by magnetic resonance imaging.⁶⁷ Cycloserine is contraindicated in patients with a history of either seizures or depression. Whenever this drug is used, serum concentrations must be monitored. Optimal treatment concentrations are between 20 and 35 mg/dL, and adverse effects are more common above 30 mg/dL. Cycloserine should be introduced slowly to avoid CNS toxicity.^{31,57,87} Toxicity, which can be potentiated by alcohol, usually appears within the first 2 weeks of therapy and ceases upon discontinuation. Because cycloserine is renally excreted, patients with impaired GFR may be predisposed to toxicity; it is removed by hemodialysis.³¹ Although no teratogenic effects were noted in three women exposed to cycloserine during the first trimester of pregnancy, cycloserine is not recommended for use during pregnancy. Cord blood concentrations are approximately 70% of serum concentrations, and no adverse effects occurred in breastfed infants. Consequently, cycloserine is considered to be safe in women who are breastfeeding.¹⁴ Reports of overdose are lacking in the English medical literature.

OTHER ANTIMYCOBACTERIALS

Ethionamide

Aminosalicilic acid

ETHIONAMIDE

Ethionamide, a congener of INH, is a prodrug with a mycotoxic intermediary metabolite thought to have a similar mechanism of action as INH, causing cell death from disruption of mycolic acid biosynthesis. Ethionamide is rapidly absorbed, widely distributed, and crosses the blood–brain barrier. Oral doses yield peak serum concentrations within approximately 3 hours of administration. The half-life is approximately 2 hours. The most common adverse symptoms associated with ethionamide are GI irritation and anorexia. Toxic effects such as orthostatic hypotension, depression, and drowsiness are common. Rash, purpura, and gynecomastia are observed, as are tremor, paresthesias, and olfactory disturbances. Approximately 5% of patients receiving ethionamide develop hepatitis; patients using this medication should be screened intermittently for hepatic injury. Treatment for toxicity involves withholding ethionamide therapy.⁴⁹

Birth defects were observed in seven of 23 newborns exposed to ethionamide in utero, although a consistent pattern of anomalies was lacking. Data regarding the presence and safety of breastfeeding on ethionamide also are lacking.¹⁴ Ethionamide is too toxic to be used as first-line therapy, but when needed, it should only be administered with another antituberculous medication because resistance develops rapidly when ethionamide is used alone.⁴⁹ Reports of death from ethionamide overdose are absent from the English literature.

para-AMINOSALICYLIC ACID

para-Aminosalicilic acid (PAS) is a structural analog of para-aminobenzoic acid and is thought to inhibit enzymes responsible for folate biosynthesis in mycobacteria but not in other organisms.⁴⁹ Despite common adverse effects, PAS is being used to a greater extent in the multidrug treatment plans for treating XDR-TB.⁸⁰ PAS is readily absorbed from the gut and is rapidly distributed in all tissues, especially the pleural fluid and caseous material. PAS has a half-life of

approximately one hour and is renally excreted. Adverse effects of PAS occur in 10% to 30% of patients and include anorexia, nausea, vomiting, diarrhea, sore throat, and malaise. Between 5% and 10% of patients receiving PAS develop hypersensitivity reactions characterized by high fever, rash, and arthralgias. Hematologic abnormalities of agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, and acute hemolytic anemia are reported.⁴⁹ PAS may be removed by hemodialysis in patients with kidney failure.⁷³ Adverse effects associated with chronic therapy may be treated by its withdrawal. Data regarding the safety of PAS in pregnancy and breastfeeding are lacking.¹⁴

Capreomycin

Capreomycin is a cyclic polypeptide currently used more frequently because of its antibacterial activity against MDR-TB and intracellular TB bacilli. TB strains resistant to more than one aminoglycoside may be susceptible to this polypeptide. Capreomycin interferes with ribosomes and inhibits protein translation but may also act by other mechanisms such as alterations in topoisomerase or the glyoxylate shunt pathway.⁴² Because of poor absorption after oral dosing, capreomycin must be administered intramuscularly. Toxicity associated with capreomycin use includes tinnitus, hearing loss, proteinuria, and electrolyte disturbances, although severe acute kidney injury is rare. Eosinophilia, leukocytosis, and rashes are described. Pain and sterile abscesses at the site of capreomycin injection are reported.⁴⁹ Data are lacking regarding the safety of capreomycin in pregnancy and breastfeeding.¹⁴

Many other antibiotics and immunomodulators that have been primarily overlooked or rejected for the management of TB are increasingly being used as part of multidrug regimens against resistant strains. Discussed more extensively in [Chap. 57](#), these include fluoroquinolones such as ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, sparfloxacin, macrolides such as clarithromycin, aminoglycosides such as amikacin, streptomycin, kanamycin, interferon, amoxicillin–clavulanate, linezolid, and clofazimine.⁸⁰

SUMMARY

- In overdose, certain antituberculous medications are of significant toxicologic concern.
- Patients acutely poisoned with INH require immediate and appropriate action to reverse seizures, acidemia, and coma beginning with the specific antidote pyridoxine. Pyridoxine is effective therapy, commonly augmented by benzodiazepines.
- Although less common than previously believed, hepatocellular injury resulting from therapeutic dosing of INH requires regularly scheduled, frequent evaluations to prevent fulminant hepatic failure.
- With the increasing prevalence of MDR-TB and XDR-TB strains, antituberculous medications previously avoided or ignored are now being used typically in combination with two or more other antituberculous medications. Despite reduced dosages compared with those previously used, significant adverse effects remain a concern in some cases.
- Rifampin causes numerous drug–drug interactions, some involving several anti-HIV therapies. Because antituberculous therapies are commonly needed in HIV infected patients, potential interactions between rifampin and antiretrovirals should remind clinicians to remain vigilant for unanticipated adverse effects.
- Patients receiving ethambutol, PZA, and other antituberculous medications benefit from careful surveillance for specific adverse effects such as decreased visual acuity, hepatic injury, and psychiatric manifestations. Despite the toxicity of this class of drugs, poisonings are often responsive to intervention when recognized early and treated appropriately.

A14 ANTIDOTES IN DEPTH

Pyridoxine

Mary Ann Howland

INTRODUCTION

Pyridoxine (vitamin B₆), a water-soluble vitamin, is an antidote for overdoses of isonicotinic acid hydrazide (Isoniazid, INH), *Gyromitra esculenta* mushrooms, hydrazine, methylated hydrazines, and ethylene glycol. With the exception of ethylene glycol, all of these xenobiotics produce seizures by the competitive inhibition of pyridoxal-5'-phosphate (PLP). Pyridoxine overcomes this inhibition and may also enhance the less toxic pathway of ethylene glycol metabolism to form benzoic and hippuric acid, instead of oxalic acid.⁶ Hydrazine and methylated hydrazines (1,1-dimethylhydrazine, UDMH; monomethylhydrazine, MMH) are used as rocket fuels, and MMH is also found in *Gyromitra esculenta* mushrooms.³

HISTORY

Pyridoxine deficiency, which is characterized by seborrheic dermatitis, cheilosis, stomatitis, and glossitis, was first identified in 1926 but was mistakenly attributed to the absence of vitamin B₂ (Chap. 47).³¹ Ten years later, the deficiency was fully characterized and correctly recognized as a deficiency of vitamin B₆.³¹ A rare genetic abnormality that produces pyridoxine-responsive seizures in newborns was described in 1954.⁵

PHARMACOLOGY

Chemistry

The active form of pyridoxine is PLP.³¹ The alcohol pyridoxine, the aldehyde pyridoxal, and the aminomethyl pyridoxamine are all naturally occurring, related compounds that are metabolized by the body to its active form PLP.³¹ Pyridoxine was chosen by the Council on Pharmacy and Chemistry to represent vitamin B₆.³¹ Pyridoxine hydrochloride was chosen as the commercial preparation because of its stability.⁵⁵

Mechanism of Action

Pyridoxal-5'-phosphate is an important cofactor in more than 100 enzymatic reactions, including decarboxylation and transamination of amino acids, and the metabolism of tryptophan to 5-hydroxytryptamine (serotonin) and methionine to cysteine.^{23,31} In animals, iatrogenic pyridoxine deficiency produces seizures, resulting from reduced brain concentrations of PLP, glutamic acid decarboxylase, and γ -aminobutyric acid (GABA).¹⁶

Isoniazid and methylated hydrazines such as MMH interfere with the normal function of pyridoxine as a coenzyme. INH produces a syndrome resembling cerebral vitamin B₆ deficiency, which results in seizures.⁴³ Specifically, INH and other hydrazides and hydrazines inhibit the enzyme pyridoxine phosphokinase that converts pyridoxine to PLP (Fig. 58–3).²³ In addition, hydrazides directly combine with PLP, causing inactivation through the production of hydrazones that are rapidly excreted by the kidney.^{23,50} PLP is a coenzyme for L-glutamic acid decarboxylase, which facilitates the synthesis of GABA from L-glutamic acid. Animal studies suggest that interference with PLP limits the formation of GABA,^{23,50,51} which results in increased glutamic acid, thereby reducing cerebral inhibition, which contributes to the INH and methylated hydrazine–induced seizures.^{41,53} The administration of large doses of pyridoxine overcomes the deficiency.

Pharmacokinetics

Whereas pyridoxine is not protein bound, has a volume of distribution of 0.6 L/kg, and easily crosses cell membranes, PLP

is nearly entirely plasma protein bound.⁵⁵ At extrahepatic sites, pyridoxine is rapidly metabolized to pyridoxal, PLP, and 4-pyridoxic acid, with only 7% excreted unchanged in the urine.⁵⁵ After intravenous (IV) infusion of 100 mg of pyridoxine, PLP concentration increases rapidly in serum and in erythrocytes.⁵⁵ PLP rises from 37 to 2183 nmol/L in serum and from undetectable to 5593 nmol/L in erythrocytes.⁵⁵ Oral pyridoxine, in doses of 600 mg, is 50% absorbed within 20 minutes of ingestion by a first-order process, with rapid achievement of peak serum concentrations of pyridoxine, PLP, and pyridoxal.⁵⁴ The concentration of PLP appears to be tightly controlled in the serum and related to alkaline phosphatase activity.^{24,54} Oral doses of pyridoxine from 10 to 800 mg result in PLP concentrations of 518 to 732 nmol/L at 4 hours after ingestion.⁵⁴ Chronic alcoholic patients have lower baseline serum PLP concentrations because acetaldehyde enhances the degradation of PLP in erythrocytes through stimulation of an erythrocyte membrane-bound phosphatase that hydrolyzes phosphate containing B₆ compounds.³⁰

ROLE IN HYDRAZIDE- AND HYDRAZINE-INDUCED SEIZURES

Animal Studies

In a canine model of INH induced toxicity, pyridoxine reduced the severity of seizures, increased the duration of seizure free periods, and prevented death from a previously determined lethal dose of INH in a dose dependent fashion.^{13,14} Lower molar ratios prevented deaths, and higher molar ratios prevented both deaths and seizures.¹⁴ When used as single treatments for INH induced seizures, phenobarbital, pentobarbital, phenytoin, ethanol, and diazepam were ineffective in controlling seizures and death, but when combined with pyridoxine, each protected the animals from seizures and death.¹³ Other small animal experiments have documented the effectiveness of pyridoxine against MMH induced seizures when used without^{23,34,46} and with diazepam.²⁰ Anticonvulsant efficacy is also demonstrated in feline⁴² and primate⁴⁴ models.

Rat studies with intraperitoneal UDMH also demonstrate the protective effects of pyridoxine, which prevented seizures and death in a model that produced 94% mortality and 100% seizures without pyridoxine.¹⁵ Other studies in dogs and monkeys also demonstrate the effectiveness of pyridoxine in preventing seizures and mortality, and in treating seizures.⁴ Intramuscular pyridoxine protected the monkeys from death and stopped the seizures caused by IV exposure to UDMH.

Human Data

Clinical experience with pyridoxine for INH overdose in humans demonstrates favorable results.^{2,11} Rapid seizure control with no morbidity or mortality was achieved when the ratio in grams of pyridoxine administered to INH ingested ranged from 0.14 to 1.3, although in practice, most patients receive approximately gram-for-gram amounts. In five patients, the use of gram-for-gram amounts of pyridoxine resulted in the complete control of seizures and a resolution of the metabolic acidosis.⁴⁹ In eight patients with intentional INH overdoses, basic poison management, intensive supportive care, and a mean dose of 5 g of pyridoxine IV resulted in no fatalities.⁸ Seizures were controlled in a 22 month-old boy given 100 mg of IV pyridoxine after an estimated INH ingestion of 5 g.⁴³ Variable results are reported when lesser amounts of pyridoxine are used.³² Seizures were reported in two patients after ingestion of INH–pyridoxine combination tablets, although the actual amount of pyridoxine ingested was not noted.⁴⁵

In addition to controlling seizures, administration of pyridoxine also appears to restore consciousness. Two patients, who remained obtunded for as long as 72 hours after the apparent resolution of the seizures, were reported to awaken immediately after 3 to 10 g of IV pyridoxine was administered.¹⁰ A third patient who was lethargic awakened with IV pyridoxine. This suggests that mental status abnormalities associated with INH overdose (and possibly hydrazine overdoses) may be responsive to pyridoxine and may also require repetitive dosing.^{11,49} Patients treated with large doses of pyridoxine awaken more rapidly even after experiencing sustained seizure activity or status epilepticus.

Monomethylhydrazine poisoning can be encountered in a variety of clinical situations. In the aerospace industry, where MMH is used as a rocket propellant, percutaneous or inhalational poisoning may occur. Ingestion of the false morel mushroom, *Gyromitra esculenta*, can also produce toxicity when its major toxic compound, gyromitrin, is metabolized to MMH (Chap. 120).^{3,18}

The neurologic effects of MMH poisoning are similar to those of INH toxicity and include seizures and respiratory failure.¹⁶ Severe liver damage similar to INH induced hepatotoxicity is also described.⁹ As in the case of INH induced hepatotoxicity, there is no evidence that MMH induced hepatotoxicity can be treated by administration of pyridoxine.⁹

A patient who was exposed to hydrazine became comatose 14 hours later and remained comatose for 60 hours until treated with 25 mg/kg of pyridoxine.²⁵ A man with an altered consciousness who had ingested an unknown quantity of hydrazine improved after treatment with 10 g of pyridoxine.²² This improvement occurred over 24 hours and may have been unrelated to pyridoxine therapy. A severe sensory peripheral neuropathy lasting for 6 months developed one week after the overdose and was most likely a result of the hydrazine ingestion and not the pyridoxine. Six patients exposed to an

Aerozine-50 (hydrazine and UDMH) spill were effectively treated with pyridoxine after developing twitching, clonic movements, hyperactivity, or gastrointestinal symptoms.¹⁹ A patient exposed to UDMH during an explosion developed extensive burns, diverse neurologic manifestations, and electroencephalographic findings that resolved rapidly after the administration of IV pyridoxine.¹⁷

ROLE IN ETHYLENE GLYCOL

Pyridoxal-5'-phosphate is a cofactor in the conversion of glycolic acid to nonoxalate compounds ([Chap. 109](#)). Patients poisoned with ethylene glycol should receive 100 mg/d of pyridoxine IV in an attempt to shunt metabolism preferentially away from the production of oxalic acid. This approach is supported by an animal model⁶ and the study of primary hyperoxaluria,²¹ although there are no adequate studies of human ethylene glycol poisoning.³⁶

ADVERSE EFFECTS AND SAFETY ISSUES

Pyridoxal-5'-phosphate is neurotoxic to animals and humans when administered chronically in supraphysiologic doses.^{25,27,37} Delayed peripheral neurotoxicity occurred in patients taking daily doses of 200 mg to 6 g of pyridoxine for one month.^{35,40,41} Healthy volunteers given 1 or 3 g/d developed a small and large fiber distal axonopathy, with sensory findings and quantitative sensory threshold abnormalities occurring after 1.5 months at the high dose and 4.5 months at the low dose exposure. When symptoms occurred, the pyridoxine was immediately stopped, but symptoms progressed for 2 to 3 weeks ([Chap. 24](#)).⁷

Pyridoxine may also induce a sensory neuropathy when massive doses are administered, either as a single dose or over several days.^{1,26,48} Ataxia occurred in dogs receiving 1 g/kg of pyridoxine.⁴⁸ Larger doses of pyridoxine result in loss of coordination, ataxia, seizures, and death.⁴⁸ Death after pyridoxine administration was sometimes delayed for 2 to 3 days.⁴⁸

Two patients treated with 2 g/kg of IV pyridoxine (132 and 183 g, respectively) over 3 days developed severe and disabling sensory neuropathies.¹ One year later, both patients were unable to walk. Inadequate information is available to determine the maximal single acute nontoxic dose in humans; however, there appears to be a wide margin of safety. Doses of pyridoxine ranging from 70 to 375 mg/kg or doses equivalent to the milligram-per-kilogram historical dose of ingested INH have been administered without adverse effects.^{28,49}

The 0.5% chlorobutanol preservative in IV pyridoxine equates to doses of 250 to 500 mg of chlorobutanol when 5 and 10 g doses of pyridoxine are administered. Chlorobutanol is a sedative with a long elimination half-life, but doses of 600 mg were given to human volunteers without complication.^{12,47} A dose of 5 g IV pyridoxine administered over 5 minutes to five healthy volunteers produced a transient minor increase in base deficit without any alteration in the level of consciousness.²⁹

PREGNANCY AND LACTATION

Pyridoxine is Food and Drug Administration pregnancy category A. The recommended daily allowance for pyridoxine in pregnancy is 2.2 mg. There has never been a controlled trial in pregnant women of gram doses of pyridoxine, but the benefit of using pyridoxine for INH induced seizures would clearly exceed the theoretical risk to the fetus. Pyridoxine enters breast milk and is considered compatible with breastfeeding. However, concentrations of pyridoxine in breast milk after maternal gram doses of pyridoxine have not been studied.

DOSING AND ADMINISTRATION

A safe and effective pyridoxine regimen for INH overdoses in adults is 1 g of pyridoxine for each gram of INH ingested, or 70 mg/kg in a child both to a maximum of 5 g.⁴⁹ These doses are sufficient in the majority of patients, but the dose can be repeated if necessary. The best way to administer pyridoxine in a patient after an INH overdose has not been established. For a patient who is actively seizing, pyridoxine may be given by slow IV infusion at approximately 0.5 g/min until the seizures stop or the maximum dose has been reached. When the seizures stop, the remainder of the dose should be infused over 4 to 6 hours to maintain pyridoxine availability while the INH is being eliminated. The dose should be repeated if seizures persist or recur or if the patient exhibits mental status depression, which could be an indication of persistent neurotoxicity and electrical status epilepticus. If IV pyridoxine is unavailable, oral pyridoxine should be administered.^{39,52}

For hydrazine and methylated hydrazines (ie, MMH, UDMH) poisoning, there is no established dose.⁵³ Using the same dosage regimen as in the case of INH poisoning is theoretically reasonable and appropriate, although it has never been tested in humans.

FORMULATION

Pyridoxine hydrochloride is available parenterally at a concentration of 100 mg/mL with a 1 mL fill in a 2 mL vial with 0.5% chlorobutanol as the preservative and 1.4 µg/mL aluminum from APP Pharmaceuticals.³⁸ Thus, a 5 g IV dose of pyridoxine requires fifty 100 mg/mL vials. This is an exception to the rule that appropriate doses of medications rarely require multiple vials and certainly not of this magnitude. This quantity also emphasizes the necessity of maintaining an adequate supply in the emergency department as well as in the pharmacy.³³ Oral pyridoxine is available in many tablet strengths from 10 to 500 mg depending on the manufacturer.

SUMMARY

- Pyridoxine and a benzodiazepine should be used to achieve synergistic control of INH or MMH poisoning. An adequate dose of IV pyridoxine is 70 mg/kg to a maximum of 5 g and repeated once as needed.
- Five grams of IV pyridoxine requires administration of fifty 100-mg/mL vials.
- Adequate stocks should be ensured in the ED and pharmacy.
- If IV pyridoxine is unavailable, oral pyridoxine may be used.

59 ANTIMALARIALS

James David Barry

The malaria parasite has caused untold grief throughout human history. The name originated from Italian *mal aria* (bad air) because the ancient Romans believed the disease was caused by the decay in marshes and swamps and was carried by the malodorous “foul” air emanating from these areas.¹⁰ In the 1880s, both the *Plasmodium* protozoa as well as its mosquito vector were identified.¹⁰ Today, 40% of the world’s population lives in areas where malaria is endemic. More than 500 million people develop acute malaria infection, and an estimated one million die from the infection each year.^{2,10,46} Most of these deaths are from *Plasmodium falciparum* infections of young children in Africa.⁵ To put this into perspective, it is estimated that two children die from malaria every minute worldwide.⁵⁵ Included among those at risk of becoming infected are 50 million travelers from industrialized countries who visit the developing countries each year. Despite using prophylactic medications, 30,000 of these travelers will acquire malaria.¹⁰¹

MALARIA OVERVIEW

Malaria is an infection of protozoan parasites in the *Plasmodium* genus with a unique lifecycle involving the *Anopheles* mosquito as vector. Today malaria is primarily endemic in tropical and subtropical areas worldwide. It was once endemic in temperate areas, including Western Europe and the United States, but economic development and improvements in public health hastened its retreat.⁴⁵ Malaria was fully eradicated from the United States between 1947 and 1951 due in large part to the powerful insecticidal effects of dichloro-diphenyl-trichloroethane (DDT).⁴⁵ The emergence of DDT-resistant *Anopheles* mosquitoes and chloroquine resistant *Plasmodium* spp have impeded eradication in other parts of the world.⁴⁵

Malaria has a unique lifecycle (Fig. 59–1) beginning with inoculation of sporozoites from an infected female *Anopheles* saliva. The sporozoites travel to the liver, where they invade the host’s hepatocytes and undergo asexual division (asexual exoerythrocytic cycle), ultimately causing rupture of the infected hepatocyte (tissue schizont) and release of thousands of merozoites into the blood stream.⁹ The tissue phase is complete at this point with the exception of *Plasmodium vivax* and *Plasmodium ovale*, which can remain dormant in liver cells (hypnozoites), causing recurrent infections years later. The erythrocytic cycle begins when merozoites penetrate erythrocytes (trophozoites), undergoing additional cycles of asexual division (erythrocytic schizont), leading to cell rupture and the release of a new wave of merozoites to infect additional erythrocytes. This erythrocytic cycle is responsible for the clinical manifestations of malaria. Some erythrocytic merozoites differentiate into sexual forms (macrogametocytes, female and microgametocytes, male). Ingestion of both sexual forms by the female *Anopheles* during a blood meal allows fertilization and zygote formation in the mosquito midgut epithelium (sporogonic cycle), ultimately leading to rupture of an oocyst and release of sporozoites that migrate to the salivary glands, awaiting injection into another victim.¹²³

FIGURE 59–1. Life cycle stages during which antimalarials exert their effects.

Five *Plasmodium* spp cause malaria in humans (Table 59–1). The majority of cases worldwide are caused by *P. falciparum* and *P. vivax*, with *P. falciparum* responsible for the overwhelming majority of deaths.⁷⁷ Traditional teaching highlights the synchronization of blood parasite cycles causing a somewhat predictable fever periodicity, described as tertian or quartan fever depending on the causative organism. These classic periodic fevers are rarely observed in Western countries because symptomatic cases are diagnosed earlier than in the past.⁹ The routine use of antipyretics may also contribute to atypical presentations.

TABLE 59–1. *Plasmodium* spp Affecting Humans

Species	Distribution	Fever Cycle (days)	RBC Preference	Parasitemia Levels	Comments
<i>P. falciparum</i>	Widespread throughout tropics	2 or less (sub-tertian)	All ages	Can be high	Most fatalities
<i>P. knowlesi</i>	Malaysia and neighboring countries	1	All ages	Can be high	Zoonosis (primary host Macaque monkey) severe disease
<i>P. malariae</i>	Patchy worldwide	3–4 (quartan)	Old	Low	Chronic infections, late recrudescence
<i>P. ovale</i>	Africa	2–3 (tertian)	Young	Low	Relapses/hepatic hypnozoites
<i>P. vivax</i>	Predominantly Asia	2–3 (tertian)	Young	Low	Relapses/hepatic hypnozoites

Unlike the other forms of human malaria, *Plasmodium knowlesi* is a true zoonosis, the natural host being macaques (*Macaca* spp) and related monkey species. Natural transmission of a nonhuman *Plasmodium* spp to humans was thought to be rare, but increasing numbers of *P. knowlesi* malarial infections have been reported in and around Malaysia, Indonesia, and Southeast Asia, causing scientists to include this agent as a potential human pathogen.⁵⁵

ANTIMALARIAL HISTORY

It is somewhat ironic that despite sophisticated drug development methods and advanced technology of the 21st century, the most widely used old treatments (quinine and its derivatives) and the best new regimens (artemisinins) have both been used for centuries as ancient herbal remedies derived from plants.

The bark of the cinchona tree, the first effective remedy for malaria, was introduced to Europeans more than 350 years ago.¹¹⁷ The toxicity of its active ingredient, quinine, was noted from the inception of its use. Pharmaceutical advances occurred, funded largely by the US military during World War II, yielding 4-aminoquinolines, 8-aminoquinolines, and novel antifolates. To combat emerging strains of drug resistant *P. falciparum* that developed during the Vietnam conflict, alternate quinine derivatives (amino alcohols) were developed.^{112,117} Other drugs used to treat malaria include the folate inhibitors, selected antibiotics, the sulfonamide sulfadoxine, the tetracyclines, and the macrolides ([Chap. 57](#)).

With the introduction of each new drug, resistance developed, particularly in Oceania, Southeast Asia, and Africa.^{112,117} In some places, quinine is again the first-line therapy for malaria.⁶² In the past 2 decades, the search for active xenobiotics has returned to a natural product, the Chinese herb qinghaosu. The active metabolite, dihydroartemisinin, is common to all the endoperoxidases. These drugs are primarily used as part of an artemisinin-based combination therapy (ACT), which is recommended by the World Health Organization (WHO) as the preferred treatment of malaria in drug-resistant areas.^{2,10} With increased leisure travel, a greater number of North Americans are taking prophylactic medications with potential toxicity.

This chapter highlights the toxicity of the most commonly used antimalarials using the structural and mechanistic classification outlined in [Table 59–2](#).

TABLE 59–2. Antimalarial Classification and Mechanisms

<i>Class</i>	<i>Examples</i>	<i>Antimalarial Mechanism</i>	<i>Lifecycle Stage Effect</i>
Amino alcohols	Halofantrine Lumefantrine Mefloquine Quinine	Inhibit heme digestion	Erythrocytic cycle ^a
4-aminoquinolines	Amodiaquine Chloroquine Hydroxychloroquine Piperaquine	Inhibit heme digestion	Erythrocytic cycle ^a
8-aminoquinolines	Diethylprimaquine Primaquine	Oxidant stress	Liver stages hypnozoitocidal
Endoperoxides	Artemether Artesunate Artemisinin Artemisone Dihydroartemisinin	Unknown but oxidant stress likely contributes	Erythrocytic cycle ^a
Antifolates	Cycloguanil Chlorproguanil Dapsone Proguanil Pyrimethamine Trimethoprim	Inhibit dihydro-folate reductase	(All growing stages) Erythrocytic cycle ^a Exo-erythrocytic cycle ^b
Antibiotics	Sulfonamides Sulfadoxine	Inhibit dihydropteroate synthetase	Erythrocytic cycle ^a
	Cyclines Doxycycline Tetracycline	Inhibit protein synthesis	Erythrocytic cycle ^a
	Macrolides Azithromycin Clindamycin	Apicoplast disruption	Erythrocytic cycle ^a
Napthoquinones	Atovaquone	Inhibit mitochondrial respiration	Mosquito sporogonic cycle ^c

^aBlood schizonticidal and blood gametocidal. ^bLiver schizonticidal but not effective against hypnozoites.

^cAltered oocyst development.

AMINO ALCOHOLS

Antimalarial Mechanism

Unlike humans, who detoxify heme through the use of heme oxygenase producing the bile pigment biliverdin, *Plasmodium* spp convert heme to the nontoxic relatively inert compound hemozoin. Amino alcohols and 4-aminoquinolines concentrate in parasite food vacuoles, where they inhibit the ability of the parasite to detoxify hemozoin, leading to accumulation of toxic heme byproducts and parasite death.^{94,123} In resistant parasites, these antimalarials fail to concentrate in food vacuoles because of increased drug efflux. This resistance is thought to be conferred through amplification of a transmembrane pump. Interestingly, tricyclic antidepressants, phenothiazines, and calcium channel blockers have been shown to reverse resistance in experimental models.⁹⁴

Quinine

The therapeutic benefits of the bark of the cinchona tree have been known for centuries. As early as 1633, cinchona bark was used for its antipyretic and analgesic effects,⁷⁶ and in the 1800s, it was used for the treatment of “rebellious palpitations.”¹¹⁷ Quinine, the primary alkaloid in cinchona bark, was the first effective treatment for malaria. Additionally, because of a reported curarelike action, quinine has also been used as a treatment for muscle cramps. Because of its extremely bitter taste similar to that of heroin, quinine is used as an adulterant in drugs of abuse. Small quantities of quinine can be also found in some tonic waters.

High doses of quinine and other cinchona alkaloids are oxytocic, potentially leading to abortion or premature labor in pregnant women. Because of this, quinine has been used as an abortifacient ([Chap. 21](#)).⁷⁸ Chloroquine continues to be used for this purpose in some parts of the developing world.^{12,95} Neither is safe for this purpose because of their narrow toxic-to-therapeutic ratio.

Pharmacokinetics and Toxicokinetics. See [Table 59–3](#) for the pharmacokinetic properties of quinine. Quinine and quinidine are optical isomers and share similar pharmacologic effects as class IA antidysrhythmics and antimalarials. Both are extensively metabolized in the liver, kidneys, and muscles to a variety of hydroxylated metabolites. Quinine undergoes transplacental distribution and is secreted in breast milk.

TABLE 59–3. Pharmacokinetic Properties of Antimalarials

<i>Antimalarial</i>	<i>Bioavailability (%)</i>	<i>Time to Peak Hours (oral)</i>	<i>Protein Bound (%)</i>	<i>Volume of Distribution (L/kg)</i>	<i>Half-Life</i>	<i>Urinary Excretion (%)</i>	<i>Comments</i>
Artemisinin	Limited	—	Large	—	2–5 h	—	Metabolism largely through cytochrome P450 system.
Chloroquine	80	2–5	50–65	>100	40–55 d	55	—
Dapsone	90	3–6	70–80	0.5–1	21–30 h	20	—
Halofantrine	Low, varies	4–7	—	>100	1–6 d	—	Active metabolite.
Mefloquine	>85	8–24	98	15–40	15–27 d	<1	Hepatic metabolism. Inactive metabolite.
Primaquine	74	1–3	—	2.9	5–7 h	4	Active Metabolites primarily responsible for therapeutic and toxic effects.
Pyrimethamine	>95	2–6	87	3	3–4 d	16–32	—
Quinine	76	1–3	93	1.8–4.6	9–15 h	20	Protein binding increased in alkaline environments. Urinary excretion increased with acidic urine.

— = poorly studied or unknown.

Pathophysiology. Quinine overdose affects multiple organ systems through a number of different pathophysiologic mechanisms. Studies evaluating mechanisms of toxicity have focused on those organ systems primarily affected. Outcomes appear to be most closely related to the degree of cardiovascular dysfunction.⁴²

Quinine and quinidine share anti- and prodysrhythmic effects primarily from an inhibiting effect on the cardiac sodium channels and potassium channels (**Chaps. 16 and 64**).⁴³ Blockade of the sodium channel in the inactivated state decreases inotropy, slows the rate of depolarization, slows conduction, and increases action potential duration. Inhibition of this rapid inward sodium current is increased at higher heart rates (called use-dependent blockade), leading to a rate-dependent widening of the QRS complex.^{117,126}

Inhibition of the potassium channels suppresses the repolarizing delayed rectifier potassium current, particularly the rapidly activating component,¹²⁶ leading to prolongation of the QT interval. The resultant increase in the effective refractory period is also rate dependent, causing greater repolarization delay at slower heart rates and predisposing to torsade de pointes. As a result, syncope and sudden dysrhythmogenic death may occur. An additional α -adrenergic antagonist effect contributes to the syncope and hypotension occurring in quinine toxicity.

Inhibition of the adenosine triphosphate (ATP)–sensitive potassium channels of pancreatic β cells results in the release of insulin, similar to the action of sulfonylureas (**Chap. 53**).³² Patients at increased risk of quinine induced hyperinsulinemia include those patients receiving high dose intravenous (IV) quinine, intentional overdose, and patients with other metabolic stresses (eg, concurrent malaria, pregnancy, malnutrition, and ethanol consumption).^{21,63,86,90,114}

The mechanism of quinine induced inhibition of hearing appears to be multifactorial.¹¹² Microstructural lengthening of the outer hair cells of the cochlea and organ of Corti occurs.⁴⁸ Additionally, vasoconstriction and local prostaglandin inhibition within the organ of Corti may contribute to decreased hearing.¹¹² Inhibition of the potassium channel may impair hearing and produce vertigo because it is known that the homozygous absence of gene products that form part of some potassium channels (Jervell and Lange-Nielson syndrome) causes deafness and prolonged QT intervals (**Chaps. 16 and 26**).¹¹¹

Although older theories suggested that quinine caused retinal ischemia, the preponderance of evidence points to a direct toxic effect on the retina.⁴⁹ Electroretinographic studies demonstrate a rapid and direct effect on the retina (decreased potentials) within minutes after doses of quinine.⁴⁴ These early retinographic changes, as well as histologic lesions in photoreceptor and ganglion cell layers, provide evidence of direct damage.⁴⁴ Changes in the electrooculogram suggest changes in the retinal pigment epithelium and parallel changes in visual acuity. In contrast, no electrophysiologic, angiographic, or morphologic experimental evidence for retinal ischemia has been found.⁴⁹ Quinine may also antagonize cholinergic neurotransmission in the inner synaptic layer.

Quinine has direct irritant effects on the gastrointestinal (GI) tract and stimulates the brainstem center responsible for nausea and emesis.¹¹⁷

Clinical Manifestations. Quinine overdose typically leads to GI complaints, tinnitus, and visual symptoms within hours, but the time course varies with the formulation ingested, coingestants, patient characteristics, and other case-specific

details. Significant overdose is heralded by cardiovascular and central nervous system (CNS) toxicity. Death can occur within hours to days, usually from a combination of shock, ventricular dysrhythmias, respiratory arrest, or acute kidney failure (AKI).

Patients receiving even therapeutic doses often experience a syndrome known as “cinchonism,” which typically includes GI complaints, headache, vasodilation, tinnitus, and decreased hearing acuity.^{76,117} Vertigo, syncope, dystonia, tachycardia, diarrhea, and abdominal pain are also described.^{51,67,86}

Quinine toxicity is closely correlated with total serum concentrations, but only the non protein bound portion is likely responsible for toxic effects. However, because free and total quinine concentrations vary widely from person to person,³⁹ a single quinine concentration may not always correlate with clinical toxicity. In general, serum concentrations greater than 5 µg/mL may cause cinchonism, greater than 10 µg/mL visual impairment, greater than 15 µg/mL cardiac dysrhythmias, and greater than 22 µg/mL death.⁸ Similar concentrations in individuals who are severely ill with malaria do not necessarily result in as severe toxicity because of the increase α_1 -acid glycoprotein and consequent reduction in free fraction of quinine present.^{102,106}

The margin between therapeutic and toxic dosing of quinine is very small. It is not surprising that patients taking therapeutic doses frequently develop toxicity because the recommended range of serum quinine concentrations for treatment of falciparum malaria is 5 to 15 µg/mL, well above the concentration reported to cause cinchonism.

The average oral lethal dose of quinine is 8 g, although a dose as small as 1.5 g is reported to cause death.^{40,51} Delirium, coma, and seizures are less common, usually occurring only after severe overdoses.¹⁷

Cardiovascular manifestations of quinine use are related to myocardial drug concentrations.¹⁵ They manifest on the electrocardiogram (ECG) as prolongation of the PR interval; prolongation of the QRS complex, QT interval, and ST depression with or without T wave inversion also occur.¹¹ Patients may develop complete heart block or dysrhythmias.¹⁵ Patients taking high doses of quinine must be monitored for torsade de pointes, ventricular tachycardia, and ventricular fibrillation. Quinine toxicity can also result in significant hypotension.

Although not commonly reported, mild hyperinsulinemia and resultant hypoglycemia can occur in cases of oral quinine overdose.^{17,21,42,63,105,128,129} Hypoglycemia with elevated serum insulin concentrations after therapeutic dosing was documented in case reports complicated by severe congestive heart failure and significant ethanol consumption. Hypoglycemia is also noted in healthy patients after overdose.⁶³

Eighth cranial nerve dysfunction results in tinnitus and deafness. The decreased acuity is not usually clinically apparent, although the patient recognizes tinnitus.⁹⁹ These findings usually resolve within 48 to 72 hours, and permanent hearing impairment is unlikely.

Ophthalmic presentations include blurred vision, visual field constriction, tunnel vision, diplopia, altered color perception, mydriasis, photophobia, scotomata, and sometimes complete blindness.^{17,36,44} The onset of blindness is invariably delayed and usually follows the onset of other manifestations by at least 6 hours. The pupillary dilation that occurs is usually nonreactive and correlates with the severity of visual loss. Funduscopic examination findings may be normal but usually demonstrate extreme arteriolar constriction associated with retinal edema. Normal arteriolar caliber may be initially present, but funduscopic manifestations such as vessel attenuation and disc pallor may develop as clinical improvement occurs. Improvement in vision can occur rapidly but is usually slow, occurring over a period of months after a severe exposure. Initially, improvement occurs centrally and is followed later by improvement in peripheral vision. The pupils may remain dilated even after return to normal vision.⁴⁰ Patients with the greatest exposure may develop optic atrophy.

Hypokalemia is often described in the setting of quinine poisoning,¹⁰⁵ although the mechanism is unclear. An intracellular shift of potassium rather than a true potassium deficit is the predominant theory behind the hypokalemia associated with chloroquine,^{71,73} and the mechanism may be similar with quinine.

A number of hypersensitivity reactions are described. These are the result of antiquinine or antiquinine-hapten antibodies cross-reacting with a variety of membrane glycoproteins.^{18,57} Asthma and dermatologic manifestations, including urticaria, photosensitivity dermatitis, cutaneous vasculitis, lichen planus, and angioedema, also occur.¹¹⁴

Hematologic manifestations of hypersensitivity are rare, but include thrombocytopenia ([Chap. 22](#)), agranulocytosis, microangiopathic hemolytic anemia, and disseminated intravascular coagulation (DIC), which can lead to jaundice, hemoglobinuria, and renal failure.^{51,57} Hemolysis may also occur in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Immunogenic drug platelet complex interactions can occur even after low doses of quinine, such as those in tonic drinks. This self-limited interaction has previously been termed “cocktail purpura.”^{76,117}

A hepatitis hypersensitivity reaction,³⁸ acute respiratory distress syndrome (ARDS), and a sepsislike syndrome are also reported.⁶⁰

Diagnostic Testing. Urine thin-layer chromatography is sensitive enough to confirm the presence of quinine even after

the ingestion of tonic water.¹²⁹ Quinine immunoassay techniques are also available. Quantitative serum testing is not rapidly or widely available.

Management. Patients frequently vomit spontaneously. Emetics should not be used in the absence of vomiting because seizures, dysrhythmias, and hypotension can occur rapidly. Orogastric lavage should only be considered for patients with recent, substantial (potentially life-threatening) ingestions with no spontaneous emesis. Activated charcoal effectively adsorbs quinine and may additionally decrease serum concentrations by altering enteroenteric circulation.^{3,66}

Expectant treatment should be initiated, including oxygen, cardiac and hemodynamic monitoring, IV fluid resuscitation, and frequent ECG and blood glucose measurements.

Extracorporeal membrane oxygenation was used in one case of severe quinidine poisoning with bradydysrhythmias and refractory hypotension to stabilize the cardiovascular system while a quinidine-activated charcoal bezoar was removed and the patient metabolized the remaining quinidine.¹¹⁵ A similar approach should be considered for intractable quinine toxicity.

Cardiac. A conduction delay manifested by a QRS duration of more than 100 msec should be treated with sodium bicarbonate alkalization to achieve a serum pH of 7.45 to 7.50, as would be done in patients with cardiotoxicity associated with cyclic antidepressant overdoses (Antidotes in Depth: A5). Protein binding is increased in the setting of alkalemia, decreasing the cardiotoxic manifestations of quinine. Thus, serum alkalization with sodium bicarbonate is a logical therapeutic intervention. Sodium bicarbonate therapy is successful in case reports^{15,42,76} but has not been specifically studied. Hypertonic sodium bicarbonate may result in or worsen existing hypokalemia, potentially exacerbating the effect of potassium channel blockade.

Potassium supplementation for quinine-induced hypokalemia is controversial because experimental data from the 1960s suggest that hypokalemia is protective against cardiotoxicity and prolongs survival.^{20,71,105} Because hypokalemia can also lead to lethal dysrhythmias, supplementation for hypokalemia is presently recommended.

The QT interval should be carefully monitored for prolongation. If necessary, interventions for torsade de pointes, including magnesium administration, potassium supplementation, and overdrive pacing, should be initiated (Chap. 17).

Class IA, IC, or III antidysrhythmics and other xenobiotics with sodium channel or potassium channel blocking activity should not be used to treat quinine-overdosed patients because they may exacerbate quinine-induced conduction disturbances or dysrhythmias. The Class IB antidysrhythmics, such as lidocaine, have been used with reported success, but no clinical trials have been performed (Chap. 64).

Hypotension refractory to IV crystalloid boluses should be treated with vasopressors. Although not directly studied, direct acting vasopressors such as epinephrine, norepinephrine, and phenylephrine are recommended. An intraaortic balloon pump was successfully used for the treatment of refractory hypotension in one case report.¹⁰⁵

Ophthalmic. Fundoscopic examination, visual field examination, and color testing may be appropriate bedside diagnostic studies. Electroretinography, electrooculography, visual-evoked potentials, and dark adaptation may be helpful in assessing the injury but are not practical because they require equipment that is not portable or readily available in most clinical settings. There is no specific, effective treatment for quinine retinal toxicity,^{44,47} although hyperbaric oxygen (HBO) was used in three patients who recovered vision, but the role of HBO in that recovery was not established.^{44,129}

Hypoglycemia. A low serum glucose concentration should be supported with an adequate infusion of dextrose. Serum potassium concentration and the QT interval should be monitored during correction and maintenance. Octreotide was successfully used to correct quinine induced hyperinsulinemia in adult malaria victims.^{89,90} In volunteers, quinine induced hyperinsulinemia was suppressed within 15 minutes after a 100 µg intramuscular dose of octreotide (Antidotes in Depth: A13).⁸⁹ Octreotide should be used for cases of refractory hypoglycemia in a fashion similar to that recommended in sulfonylurea toxicity, which is 50 µg (1 µg/kg in children) subcutaneously every 6 hours (Chap. 53).

Enhanced Elimination. The effect of multiple-dose activated charcoal (MDAC) on quinine elimination was studied in an experimental human model and in symptomatic patients.⁹² In these patients, MDAC decreased the half-life of quinine from approximately 8 hours to about 4.5 hours and increased clearance by 56%.⁹² Although numerous studies show that activated charcoal decreases quinine half-life,^{13,66,92} evidence of clinical benefit is lacking. Nevertheless, because ophthalmic, CNS, and cardiovascular toxicity are related to serum concentration, it is prudent to reduce concentrations as quickly as practicable; thus, activated charcoal (0.5 g/kg) should be administered every 2 to 4 hours for about four doses unless contraindications exist.

There is conflicting evidence about a benefit of urinary acidification in enhancing clearance.^{13,102} But because of the increased potential for cardiotoxicity associated with acidification, this technique is never recommended.

Because quinine has a relatively large volume of distribution and is highly protein bound, hemoperfusion, hemodialysis, and exchange transfusion have only a limited effect on drug removal.^{13,17,102,117} Although the blood compartment can be cleared with these techniques, total body clearance is only marginally altered. After rapid tissue distribution occurs, there is little impact on the total body burden because of the large volume of distribution and extensive protein binding.

Mefloquine

Pharmacokinetics and Toxicodynamics. See Table 59–3 for the pharmacokinetic properties of mefloquine.

Clinical Manifestations. Common side effects with prophylactic and therapeutic dosing include nausea, vomiting, and diarrhea.⁸³ These side effects are noted particularly in the extremes of age and with high therapeutic dosing. Similar symptoms should be expected in acute overdose.^{114,125}

Mefloquine has a mild cardiodepressant effect—less than that of quinine or quinidine—which is not clinically significant in prophylactic dosing or with therapeutic administration. Bradycardia is commonly reported.^{25,67,83} With prophylactic use, neither the PR interval nor the QRS complex is prolonged, but QT prolongation is reported.^{34,67} Reports of torsade de pointes are rare, but the increase in QT and risk of torsade de pointes are increased when mefloquine is used concurrently with quinine; chloroquine; or, most particularly, with halofantrine.^{67,83,84,126} The long half-life of mefloquine means that particular care must be taken with therapeutic use of other antimalarials when breakthrough malaria occurs during mefloquine prophylaxis or within 28 days of mefloquine therapy to avoid potential drug–drug interactions. This risk may increase with acute overdose, although there is little clinical experience.

Mefloquine commonly has neuropsychiatric side effects. During prophylactic use, 10% to 40% of patients experience insomnia and bizarre or vivid dreams and complain of dizziness, headache, fatigue, mood alteration, and vertigo.^{103,122} Only 2% to 10% of these complications necessitate the traveler to seek medical advice or change normal activities.^{25,50,113} Predisposing factors include a past history of neuropsychiatric disorders, recent prior exposure to mefloquine (within 2 months), previous mefloquine-related neuropsychiatric adverse effects, and previous treatment with psychotropics.¹¹⁴ Women appear to be more likely than men to experience neuropsychiatric adverse effects.^{114,122}

The risk of serious neuropsychiatric adverse effects (convulsions, altered mental status, inability to ambulate because of vertigo or ataxia, psychosis, or acute neurosis) during prophylaxis is estimated to be one in 10,600 but is reported to be as high as one in 200 with therapeutic dosing.^{33,114} Seizures occur rarely with prophylaxis and therapeutic use.^{91,100} In many of these cases, there is a history of previous seizures, seizures in a first-degree relative or other seizure risk factors. Other neuropsychiatric symptoms include dysphoria, altered consciousness, encephalopathy, anxiety, depression, giddiness, and agitated delirium with psychosis. Although there is a suggestion that the severity of neuropsychiatric events is dose dependent, there does not seem to be a correlation with serum or tissue concentrations.⁵⁷ In one case report, the severe neuropsychiatric manifestations of mefloquine were reversed with physostigmine, leading the authors to suggest a possible central anticholinergic mechanism.¹¹⁰ Physostigmine is not recommended as a routine treatment for mefloquine neuropsychiatric side effects. A self-resolving postmalaria neurologic syndrome including confusion, seizures, or tremor is associated with therapeutic use of mefloquine for severe malaria.^{81,100}

The effect of mefloquine on the pancreatic potassium channel is much less than that of quinine, resulting in only a mild increase in insulin secretion.^{32,34} Symptomatic hypoglycemia has not been reported as an effect of mefloquine alone in healthy individuals, but has occurred with concomitant use of ethanol and in a severely malnourished patient with acquired immune deficiency syndrome (AIDS).^{11,34,67} In overdose, particularly when accompanied by ethanol use or starvation, hypoglycemia can be severe.

Rare events such as hypersensitivity reactions reported with prophylaxis include urticaria, alopecia, erythema multiforme, toxic epidermal necrolysis, myalgias, mouth ulcers, neutropenia, and thrombocytopenia.^{72,83,103,108} It is unclear which, if any, would be significant after overdose. ARDS was linked to therapeutic dosing in one case.¹¹⁹

In therapeutic use, mefloquine is associated with an increased incidence of stillbirth compared with quinine and a group

of other antimalarials.⁸⁵ Mefloquine was not, however, linked to an increased incidence of abortion, low birth weight, mental retardation, or congenital malformations. The implications of overdose in the absence of malaria are unknown, but fetal monitoring should be instituted.

The consequences of excessive dosing and overdose are not only severe but also prolonged and potentially permanent. Mefloquine overdose led to acute hearing loss and gradual resolution of acute symptoms over one year in one case and persistent symptoms even after one year in another.⁶⁵ After ingesting 5.25 g of mefloquine over 6 days, a man had prolonged prothrombin time resolving in 5 days and weakness persisting for 2 months after resolution of the acute symptoms.¹⁹ A fourth case involved coingestion of 2.5 times the usual therapeutic doses of mefloquine, chloroquine, and sulfadoxine–pyrimethamine over 3 days. The man had encephalopathy which had not resolved 8 months later.²³

Management. In overdose, treatment is primarily supportive with monitoring for potential adverse effects. Decontamination with activated charcoal is indicated if the patient presents soon after the ingestion. Specific monitoring for ECG abnormalities, hypoglycemia, and liver injury should be provided. Patients should also be followed for CNS and cranial nerve complications.

In two patients with kidney failure who received mefloquine, prophylactic hemodialysis did not remove mefloquine.³⁰ Given the large volume of distribution and high degree of protein binding of mefloquine, extracorporeal elimination techniques are unlikely to be effective.

Halofantrine

Because of erratic absorption, the potential for lethal cardiotoxicity, and concern for cross resistance with mefloquine, halofantrine is not presently recommended for malaria prophylaxis by the WHO.^{2,114}

Pharmacokinetics and Toxicodynamics. See Table 59–3 for the pharmacokinetic properties of halofantrine.²²

Clinical Manifestations. The primary toxicity from therapeutic and supratherapeutic doses is prolongation of the QT interval and the risk of torsade de pointes and ventricular fibrillation.^{84,116} Palpitations, hypotension, and syncope may occur. First degree atrioventricular (AV) block is common, but bradycardia is rare.⁸⁴ Dysrhythmias are also likely in the context of combined overdose or combined or serial therapeutic use with other xenobiotics that cause QT interval prolongation, particularly mefloquine.⁵⁶ Because the QT interval duration is directly related to the serum halofantrine concentration, dysrhythmias should be expected in overdose.^{25,84,114} Fifty percent of children receiving a therapeutic course of halofantrine will have a QT interval greater than 440 msec.¹⁰⁹

Other side effects, including nausea, vomiting, diarrhea, abdominal cramps, headache, and lightheadedness, which frequently occur in therapeutic use, are also expected in overdose.⁶⁷ Less frequently described side effects include pruritus, myalgias, and rigors. Seizures, minimal liver enzyme abnormalities, and hemolysis are described.^{67,75,120} Whether these manifestations are related to halofantrine or to the underlying malaria is not clear.

Management. Management of patients with halofantrine overdose should focus on decontamination, supportive care, monitoring for QT interval prolongation, and treatment of any associated dysrhythmias.

Lumefantrine

Lumefantrine is structurally similar to halofantrine. It is primarily used as a partner drug in the artemisinin based combination therapy artemether plus lumefantrine.

Little toxicity of lumefantrine alone or in combination is reported.¹²⁷ Studies do not show QT interval prolongation or evidence of cardiac toxicity related to lumefantrine.³⁷ Cough and angioedema were described in one case.⁶¹ As in the case of all antimalarials, it is difficult to differentiate drug related adverse events from those of malaria, comorbid diseases, or other ingested drugs, which confounds the study of potential complications.

4-AMINOQUINOLINES

The structurally related compounds chloroquine and amodiaquine were once used extensively for malaria prophylaxis. However, with the development of resistance, they are now used in fewer geographic regions. Amodiaquine is associated with a higher incidence of hepatic toxicity and agranulocytosis. In general, these xenobiotics have low toxicity when used in therapeutic doses. Because of its low toxicity, chloroquine remains the first line drug for malaria prophylaxis and treatment in areas where *Plasmodium* spp remain sensitive.

Hydroxychloroquine is similar to chloroquine in therapeutic, pharmacokinetic, and toxicologic properties.⁷⁰ The side effect profiles of the two are slightly different, favoring chloroquine use for malarial prophylaxis and hydroxychloroquine use as an antiinflammatory agent.^{67,117} Hydroxychloroquine is used in the treatment of rheumatic diseases such as rheumatoid arthritis and lupus erythematosus. In animal studies, chloroquine is two to three times more toxic than hydroxychloroquine.⁵³

Piperaquine is structurally similar to chloroquine but is primarily used in conjunction with artemisinin compounds as a component of an ACT.

Antimalarial Mechanism. The 4-aminoquinolines interfere with the digestion of heme and hemozoin formation in a manner similar to that of the amino alcohols.³⁵

Chloroquine and Hydroxychloroquine

Pharmacokinetics and Toxicodynamics. See Table 59–3 for the pharmacokinetic properties of chloroquine. Oral chloroquine is rapidly and completely absorbed and is ultimately sequestered in many organs, particularly the kidney, liver, lung, and erythrocytes.^{16,48}

Chloroquine is slowly distributed from the blood compartment to the larger central compartment, leading to transiently high whole blood concentrations shortly after ingestion.^{95,107} It is the initial high blood concentrations that are thought to be responsible for the rapid development of profound cardiorespiratory collapse typical of chloroquine toxicity. These whole blood chloroquine concentrations correlate with death.²⁹

Pathophysiology. With structural similarity to quinine, the pathophysiologic mechanisms of chloroquine and hydroxychloroquine are also similar. Most notably, sodium and potassium channel blockade are the proposed primary mechanisms of cardiovascular toxicity.¹²⁶

Although less common in quinine toxicity, hypokalemia is extremely common in chloroquine overdose. The mechanism appears to be a shift of potassium from the extracellular to the intracellular space and not a true potassium deficit.^{71,95,105}

Clinical Manifestations. Similar to quinine, chloroquine has a small toxic-to-therapeutic margin. Severe chloroquine poisoning is usually associated with ingestions of 5 g or more in adults, systolic blood pressure less than 80 mm Hg, QRS duration of more than 120 msec, ventricular fibrillation, hypokalemia, and serum chloroquine concentrations exceeding 25 $\mu\text{mol/L}$ (8 $\mu\text{g/mL}$).^{27,97}

Symptoms usually occur within 1 to 3 hours of ingestion.⁹⁷ The range of symptoms associated with chloroquine toxicity is similar to that of quinine, but the frequencies of various manifestations differ, and other features such as cinchonism are uncommon. Nausea, vomiting, diarrhea, and abdominal pain occur less commonly than with quinine.^{51,67} In contrast, respiratory depression is common, and apnea, hypotension, and cardiovascular compromise can be precipitous.⁵¹

The cardiovascular effects of chloroquine and hydroxychloroquine are similar to those of quinine, including QRS prolongation, AV block, ST and T wave depression, increased U waves, and QT interval prolongation. Hypotension is more prominent in chloroquine toxicity than with quinine.⁵¹

Significant hypokalemia in chloroquine toxicity is invariably associated with cardiac manifestations.^{28,51} In fact, the extent of hypokalemia is a good indicator of the severity of chloroquine overdose.²⁷

Neurologic manifestations include CNS depression, dizziness, headache, and convulsions.⁴⁷ Rarely, dystonic reactions occur.⁸⁷ Transient parkinsonism is also reported after excessive dosing.⁸⁷

Ophthalmic manifestations are infrequent in acute chloroquine toxicity and transient in nature.^{51,67} More severe and irreversible vision and hearing changes are described in association with the chronic use of chloroquine and hydroxychloroquine as antiinflammatory agents.^{67,79} Myopathy, neuropathy, and cardiomyopathy also occur when used for that purpose.^{10,124} Dermatologic findings and hypersensitivity reactions are similar to those associated with quinine.³⁴ Likewise, red blood cell (RBC) oxidant stress from chloroquine may result in hemolysis in patients with G6PD deficiency (Chap. 22).

Acute hydroxychloroquine toxicity is similar to chloroquine toxicity.⁵³ Side effects from therapeutic doses include

nausea and abdominal pain; hemolysis in G6PD deficient patients; and, rarely, retinal damage, sensorineural deafness, and hypoglycemia.^{52,104} Hypersensitivity reactions, including myocarditis and hepatitis, are described.^{41,69}

Management. Aggressive supportive care should be initiated, including oxygen, cardiac and hemodynamic monitoring, and large bore IV access, and serial blood glucose concentrations should be obtained. Orogastric lavage could be considered for life-threatening ingestions presenting early, but there is little evidence of efficacy. Activated charcoal adsorbs chloroquine well, binding 95% to 99% when administered within 5 minutes of ingestion.⁵⁹ The frequent development of precipitous cardiovascular and CNS toxicity should be considered before initiating any type of GI decontamination.

Early aggressive management of severe chloroquine toxicity decreases the mortality rate.⁹⁷ This includes early endotracheal intubation and mechanical ventilation. Evidence suggests that barbiturates may not be desirable for induction in patients with chloroquine overdose. When thiopental was used to facilitate intubation, its use immediately preceded sudden cardiac arrest in seven of 25 patients after chloroquine overdose.²⁹ An adequate FiO_2 , tidal volume, and ventilatory rate should be ensured.

Although theoretically any direct acting vasopressor would be beneficial in the setting of hypotension not responsive to fluid resuscitation, epinephrine is the vasopressor most extensively studied and is considered the vasopressor of choice. High doses of epinephrine were used in the original studies describing the benefits of early mechanical ventilation and the administration of diazepam and epinephrine in chloroquine poisoning.^{97,98} The epinephrine doses used in these studies are still recommended today.^{97,98} The recommended dose is 0.25 $\mu\text{g/kg/min}$, increasing by 0.25 $\mu\text{g/kg/min}$ until an adequate systolic blood pressure (greater than 90 mm Hg) is achieved.^{31,73,97,98} Clinicians should be mindful that high doses of epinephrine could exacerbate preexisting hypokalemia.

The use of diazepam to augment the treatment of dysrhythmias and hypotension is a unique use of this drug. Initial observations with regard to patients with mixed overdoses of chloroquine and diazepam suggested less cardiovascular toxicity and a potential benefit of high dose diazepam.^{27,71} Animal and human studies that followed also showed a potential benefit.^{31,97,98} When early mechanical ventilation was combined with the administration of high-dose diazepam and epinephrine in patients severely poisoned by chloroquine, a dramatic improvement in survival compared with historical control participants (91% versus 9% survival) occurred.⁹⁷ Studies in moderately poisoned patients failed to show similar benefit,²⁷ and a rat model failed to show an inotropic effect. Although the definitive study has yet to be done, high-dose diazepam therapy (2 mg/kg IV over 30 minutes followed by 1 to 2 mg/kg/d for 2–4 days) seems warranted for serious toxicity. Diazepam or an equivalent benzodiazepine should also be used to treat seizures and for sedation.

The mechanism for a potential benefit of diazepam is unclear, but multiple theories have been postulated: (1) a central antagonistic effect, (2) an anticonvulsant effect, (3) an antidysrhythmic effect by an electrophysiologic action inverse to chloroquine, (4) a pharmacokinetic interaction between diazepam and chloroquine, and (5) a decrease in chloroquine-induced vasodilation.^{71,95,97,98} (Antidotes in Depth: A23).

The use of sodium bicarbonate for correction of QRS prolongation is also controversial. Although alkalization would be expected to counteract the effects of sodium channel blockade, it could also exacerbate preexisting hypokalemia. Although case reports describe the successful use of sodium bicarbonate in conjunction with xenobiotics for massive hydroxychloroquine overdose, no clinical trials have been performed.^{64,130} Before using sodium bicarbonate in the setting of chloroquine toxicity, clinicians should consider the overall clinical status of the patient, including the suspected degree of cardiac toxicity and severity of hypokalemia.

Hypokalemia in the setting of chloroquine overdose correlates with the severity of the toxicity.^{27,71} Potassium replacement in this setting is, again, controversial because it has not been shown that potassium supplementation will improve cardiac toxicity. In fact, several reports suggest a possible protective effect of hypokalemia in acute chloroquine toxicity.^{27,71,95} This should be balanced against the fact that severe hypokalemia can itself result in lethal dysrhythmias and data suggesting severe hypokalemia (less than 1.9 mEq/L) is associated with severe, life-threatening ingestion.^{25,51,71,107} Hypokalemia could not be directly attributed as the cause of death in most cases, however.²⁷ Based on the available evidence, potassium replacement for significant hypokalemia seems warranted, but it is essential to anticipate rebound hyperkalemia as chloroquine toxicity resolves and redistribution of intracellular potassium occurs. Cases of hyperkalemia related complications are reported after aggressive potassium supplementation.^{53,64,71}

Because chloroquine and hydroxychloroquine have high volumes of distribution and significant protein binding, enhanced elimination procedures are not beneficial.^{16,51}

Piperaquine

Piperaquine was used extensively in China and Indonesia as an antimalarial until the development of piperaquine resistant strains led to the use of better alternatives. Piperaquine has since undergone a rediscovery as a viable combination with artemisinin derivatives in ACT DP (dihydroartemisinin-piperaquine) therapy. Animal studies show piperaquine to be substantially less toxic than chloroquine. Cardiovascular toxicity with piperaquine requires cumulative doses five times higher than that of chloroquine. Hepatotoxicity occurs after chronic exposure in animals. In a human study, no significant changes in ECG or in serum glucose concentration, and no postural hypotension occurred after therapeutic doses of DP.

Management. Patients with overdose should be managed with supportive measures and expectant observation, including cardiovascular and CNS monitoring.

Amodiaquine

Reports of amodiaquine toxicity suggest that involuntary movements, muscle stiffness, dysarthria, syncope, and seizures may occur.^{6,51} Amodiaquine is associated with hypersensitivity hepatitis and neutropenia in prophylactic use but not therapeutic use.²¹ There is no overdose experience reported.

8-AMINOQUINOLINES

Primaquine

Primaquine and its related compounds are the only drugs licensed for the prevention of *P. ovale* and *P. vivax* relapse caused by hepatic hypnozoites.⁷⁷ Studies using primaquine in the early 1950s led to the discovery of G6PD deficiency after those with the disease developed hemolysis when administered the drug.¹⁴ G6PD deficiency actually offers some protection against malaria because the erythrocytes of those with the disease rupture under the increased oxidative stress of the parasite's metabolism before completion of the erythrocytic cycle.

Antimalarial Mechanism. The antimalarial action of primaquine is poorly understood but thought to be related to increasing the oxidative stress of erythrocytes,¹²³ obstructing proper parasitic development.

Pharmacokinetics and Toxicodynamics. See Table 59–3 for the pharmacokinetic properties of primaquine.

Pathophysiology. Primaquine blocks sodium channels both in vitro and animal models.^{51,126} Significant cardiovascular toxicity has not been reported, although experience with primaquine overdose is limited primarily to case reports.

The predominant clinical toxicity of primaquine relates to its ability to cause RBC oxidant stress and resultant hemolysis or methemoglobinemia. Methemoglobinemia and hemolysis can even occur in normal individuals given high doses as well as those with G6PD deficiency.^{67,114}

The major complication of primaquine in therapeutic use is hemolysis in G6PD deficient individuals.³² Primaquine is contraindicated in pregnant women because of the risk of methemoglobinemia or hemolysis in the fetus. Reversible bone marrow suppression can occur.

Clinical Manifestations. Gastrointestinal irritation is common and dose related.

The extent of hemolysis in G6PD deficient individuals depends on the extent of enzyme activity, those with greater enzyme activity having less severe hemolysis than those with less enzyme activity ([Chap. 22](#)). Other variables include the dose of primaquine and comorbid conditions, such as infection, liver disease, and administration of other drugs with hemolytic activity.

Overdose with primaquine is rarely reported, and unintentional overdoses have led to methemoglobinemia requiring IV methylene blue.¹¹⁴ Acute liver failure has occurred after unintentional overdose, and fatal hepatotoxicity is described in animal models.⁶⁵

Management. Therapy should be directed at minimizing absorption with appropriate decontamination and diagnosing and then treating significant methemoglobinemia or hemolysis. Because of structural similarities with other quinolone antimalarials and animal model evidence of sodium channel blockade, cardiovascular toxicity should be anticipated with continuous monitoring and resuscitative interventions initiated as needed.

Activated charcoal would be expected to bind primaquine quite successfully if given early ([Antidotes in Depth: A1](#)). Methylene blue ([Chap. 127](#) and [Antidotes in Depth: A42](#)) should be administered for patients who are symptomatic with methemoglobinemia. Treatment of hemolysis necessitates avoiding further exposure to primaquine and possibly exchange transfusion in severe cases. Adequate hydration should be ensured to protect against hemoglobin-induced AKI. Urinary alkalization with sodium bicarbonate is controversial in this setting but may have some benefit ([Antidotes in Depth: A5](#)).

Although no clinical studies have been performed, the large volume of distribution of primaquine makes it an unlikely candidate for benefit from extracorporeal removal.

ENDOPEROXIDES

Artemisinin and Derivatives

The medicinal value of natural artemisinin, the active ingredient of *Artemisia annua* (sweet wormwood or qinghao), has been known for thousands of years. Its antimalarial properties were first recognized by Chinese herbalists in 340 A.D., but the primary active component of qinghaosu, now known as artemisinin, was not isolated until 1974.^{10,117} Artemisinin and its semisynthetic derivatives, artesunate, artemether, arteether, and dihydroartemisinin, are the most potent and rapidly acting of all antimalarials. They were introduced in the 1980s in China for the treatment of malaria, and since then millions of doses have been used in Asia and Africa. Because of their extremely short half-lives, the artemisinins are now used in combination with drugs with longer half-lives to delay or prevent the emergence of resistance. ACTs are currently recommended by the WHO for the treatment of uncomplicated malaria^{1,10} but have not been licensed for use in the United States. Only four ACTs are currently recommended by the WHO. These include artesunate plus mefloquine, artesunate plus pyrimethamine-sulfadoxine, artesunate plus amodiaquine, and artemether plus lumefantrine.

Antimalarial Mechanism. The artemesinins have a unique structure containing a 1,2,4-trioxane ring. The endoperoxide linkage within this ring is cleaved when it comes into contact with ferrous iron, releasing free radicals that destroy the parasite.⁴ Artemisinin is the only known natural product to contain a 1,2,4-trioxane ring, and although chemical synthesis is possible, thus far it has not been financially advantageous.

Pharmacokinetics and Toxicodynamics. See [Table 59–3](#) for the pharmacokinetic properties of artemisinin. Similar to its proposed efficacy, the toxicity of artemisinin is thought to be a result of the ability of the trioxane molecular core to form

intracellular free radicals, particularly in the presence of heme. In animals, damage to brainstem nuclei is consistently produced after prolonged, high-dose, and parenteral administration.¹¹⁴ Sustained CNS exposure from slowly absorbed or eliminated artemisinins is considered markedly more neurotoxic than intermittent brief exposure that occurs after oral dosing.¹¹⁴ Embryonic loss is also observed in animals.¹¹⁴

Clinical Manifestations. In contrast to the experience with animals, the experience of more than 8000 human study participants shows that these drugs have a very low incidence of side effects.¹¹⁴ Uncommon side effects include nausea, vomiting, abdominal pain, diarrhea, and dizziness.

Prospective studies have failed to identify adverse neurologic outcomes.^{58,114} Rare reports of adverse CNS effects during therapeutic use suggest the possibility of CNS depression, seizures, or cerebellar symptoms after intentional self poisoning. In children with cerebral malaria, a higher incidence of seizures and a delay to recovery from coma were noted in a comparison with quinine.¹²¹ No neurologic difference was noted in long-term follow up. In an artemether–quinine comparative trial of adults with severe malaria, recovery from coma was also prolonged in the artemether group.¹¹⁸ Rare patients receiving an artemisinin derivative in two other studies experienced transient dizziness or cerebellar signs.^{74,93} Most recovered within days. One patient in each study had prolonged symptoms lasting 1 month and 4 months, respectively, but both ultimately recovered.^{74,93}

When serial ECGs were obtained, a small but statistically significant decrease in heart rate was noted coincident with peak drug concentrations.⁷⁴ In one therapeutic trial, 7% of adult patients receiving artemether had an asymptomatic QT interval prolongation of at least 25%.¹¹⁸ Changes in the QRS are not reported.

Although uncommon, neutropenia, reticulocytopenia, anemia, eosinophilia, and elevated aminotransferases are reported.¹¹⁴ Acute ACT overdose is rarely reported outside large population-based studies. Morbidity and mortality of overdose are frequently difficult to differentiate from those of the underlying malarial disease and coingestants.

ANTIFOLATES AND ANTIBIOTICS

Antimalarial Mechanism

Proguanil, pyrimethamine, and the antibiotic trimethoprim interfere with malarial folate metabolism by inhibiting dihydrofolate reductase at concentrations far lower than that required to produce comparable inhibition of mammalian enzymes.¹¹⁷ Dapsone and sulfonamide antibiotics also disrupt malarial folate metabolism, but by inhibiting a different enzymatic reaction; dihydropteroate synthase. Slow onset of action and concerns for the development of resistance have led to the use of these antibiotics in synergistic combinations leading to inhibition of folate metabolism at two different sites.

Pharmacokinetics and Toxicodynamics

See Table 59–3 for the pharmacokinetic properties of pyrimethamine and dapsone.

Genetic polymorphism is described in the metabolism of proguanil and dapsone.^{54,96} This may be the cause of the significant hypersensitivity reactions noted with dapsone.⁹⁶

Clinical Manifestations

The side effects of proguanil during prophylaxis include nausea, diarrhea, and mouth ulcers.⁶⁷ Because of the interference with folate metabolism, megaloblastic anemia is a rare complication. Megaloblastic bone marrow toxicity is reported in patients with chronic kidney disease (CKD).¹¹⁴ Folate supplementation may be required in pregnancy and CKD to avoid this complication.³³ Rarely, neutropenia, thrombocytopenia, rash, and alopecia are also noted.³³ In a single case report, hypersensitivity hepatitis was described.³³ When used to treat malaria, atovaquone–proguanil causes vomiting, sometimes severe, in a significant portion of patients (15%–45%).¹¹⁴ This combination is also associated with elevated aminotransferases.⁹⁴ Unintentional or deliberate overdose has caused little serious toxicity.¹¹⁴

Overdose of pyrimethamine alone is rare. In children, it results in nausea, vomiting, a rapid onset of seizures, fever, and tachycardia.^{7,51} Blindness, deafness, and mental retardation have followed.^{7,51} Seizures were attributed to sulfadoxine–pyrimethamine in an overdose of 12 tablets over 2 days (the usual dose is three tablets taken once).⁸² It is unclear whether the chronic neurologic deficits described in case reports are attributable to direct toxicity of pyrimethamine on the CNS or to complications of toxicity such as status epilepticus.^{7,51} Chronic high dose use may be associated with a megaloblastic anemia, requiring folate replacement.⁷

The sulfonamides, including the sulfone dapsone, have a long history of causing idiosyncratic reactions, including neutropenia, thrombocytopenia, eosinophilic pneumonia, aplastic anemia, neuropathy, and hepatitis.^{67,114} The rare occurrence of life-threatening erythema multiforme major and toxic epidermal necrolysis, associated with pyrimethamine–sulfadoxine prophylaxis, has limited the use of this combination for prophylaxis.

Acute ingestion of dapsone may result in nausea, vomiting, and abdominal pain.⁵¹ After overdose, dapsone produces RBC oxidant stress, leading to methemoglobinemia and, to a much lesser extent, sulfhemoglobinemia through formation of an active metabolite (Chap. 127).^{24,68} The onset of hemolysis may be either immediate or delayed. Dapsone, in particular, is known for its tendency to cause prolonged methemoglobinemia. Other symptoms, particularly tachycardia, dyspnea, dizziness, visual hallucinations, seizure, syncope, and coma resulting from end-organ hypoxia, can occur.^{24,51} Additional effects described in overdose include hepatitis and peripheral neuropathy.⁵¹

Management

Folate supplementation should be considered after an overdose of proguanil or pyrimethamine (Antidotes in Depth: A10). Other efforts should include supportive care.

After dapsone ingestion, clinically significant methemoglobinemia should be treated with methylene blue and possibly cimetidine (Chap. 127 and Antidotes in Depth: A42). There is no antidote for sulfhemoglobinemia, but it constitutes an insignificant portion of total hemoglobin. Both hemodialysis and MDAC enhance elimination of dapsone during therapy.⁸⁰ MDAC is routinely recommended in the treatment of dapsone overdose.⁶⁸ Required support may include RBC transfusion and urinary alkalinization if hemolysis is extensive (Antidotes in Depth: A5).

NAPTHOQUINONES

Atovaquone

Atovaquone inhibits the de novo pyrimidine synthesis that is necessary for protozoal survival and replication but is unnecessary in mammalian cells. Based on its beneficial side effect profile, many North American physicians are switching from mefloquine to atovaquone–proguanil for routine antimalarial prophylaxis for travelers. Atovaquone and proguanil may now be the most common antimalarials used in North America. The price of this combination previously limited its use mainly to travelers from affluent countries.²⁵ The availability to patients from other countries may increase because the generic form of this combination became available in late 2011.

Atovaquone alone, primarily used to treat *Pneumocystis jiroveci* in patients with AIDS, is relatively well tolerated.⁸⁸ Side effects include maculopapular rash, erythema multiforme (rarely), GI complaints, and mild aminotransferase elevations. Three cases of 3 to 42 fold overdose or excess dosing have been reported.²⁶ No symptoms occurred in one case (at three times therapeutic serum concentration). Rash occurred in another, and in the third case, methemoglobinemia was attributed to a simultaneous overdose of dapsone.

SUMMARY

- Malaria is a parasitic infection of human erythrocytes caused by protozoan parasites in the *Plasmodium* genus with a unique lifecycle involving the *Anopheles* mosquito as the vector. It is primarily endemic in tropical and subtropical areas worldwide.
- The antimalarial properties of quinine have been known for centuries. Therapeutic dosing can result in a unique symptom complex known as “cinchonism.” Significant overdose is heralded by cardiovascular and CNS toxicity.
- The development of resistance has limited the use of chloroquine to specific geographic regions harboring susceptible malarial strains. Rapid development of cardiorespiratory collapse is typical of chloroquine toxicity. High dose epinephrine and valium are recommended for the treatment of serious chloroquine toxicity.
- Primaquine and dapsone produce significant oxidant stress, resulting in methemoglobinemia and often hemolysis.
- Because of their extremely short half-lives, artemisinins are used in combination with drugs with longer half-lives to delay or prevent the emergence of resistance. Little is known of the acute toxicity after overdose of the newest artemisinin based medications.

E. CARDIOPULMONARY MEDICATIONS

CASE STUDY 4

History A 48 year-old woman was brought to the hospital by emergency medical services (EMS). According to the paramedics, they were called to the house after the patient sent a text message to a friend saying that she no longer wanted to live. The friend went to the patient's house and called 911 to have the police break down the door when no one answered. The patient was found on her bed with a suicide note. The friend related that the patient had migraine headaches, but did not know what medications she took.

EMS personnel reported that on the scene the patient was lethargic with the following vital signs: blood pressure, 70/40 mm Hg; pulse, 25 beats/min; and respiratory rate, 8 breaths/min. EMS started the patient on oxygen via nasal cannula, inserted an intravenous catheter, started 0.9% sodium chloride running wide open, and administered 0.5 mg of atropine before arrival to the hospital.

Physical Examination On arrival to the hospital, the patient had the following vital signs: blood pressure, 76/42 mm Hg; pulse, 35 beats/min; respiratory rate, 10 breaths/min; temperature, 98.3°F; O₂ saturation, 99% on room air; end-tidal CO₂, 38 mm Hg; and rapid reagent bedside glucose, 58 mg/dL. Physical examination was notable for pupils that were 2 to 3 mm and sluggishly reactive to light. Gag reflex was intact, and there were no secretions, pills, or blood in the mouth. The patient's chest was clear, and other than bradycardia, her cardiac examination was normal. The abdomen was soft with normal bowel sounds, and her skin was without diaphoresis or pallor. The patient responded to sternal rub and opened her eyes but mumbled incoherently. She moved all four extremities and was able to localize pain.

Initial Management Dextrose (50 g IV) and naloxone (0.04 mg followed by 0.08 mg and 0.4 mg IV) were given with no clinical response. Blood samples were sent for a complete blood count, electrolytes, ethanol, and acetaminophen (APAP), and an electrocardiogram (ECG) was ordered.

What Is the Differential Diagnosis?

Many xenobiotics cause bradycardia (Table 17–2), but this patient has the combined features of hypotension and bradycardia. Here, the differential diagnosis is more narrow, with the most common causes listed in Table CS4–1.

TABLE CS4–1. Differential Diagnosis

Most Common Toxicologic Causes of Combined Hypotension and Bradycardia

α_2 -Adrenergic agonists	Calcium channel blockers
β -Adrenergic antagonists	Cardioactive steroids
Antidysrhythmics (Class I)	Opioids
Baclofen	

What Clinical Factors Help Narrow the Differential Diagnosis? Often, the physical examination provides significant insight into the diagnosis. Patients who overdose with either opioids or α_2 -adrenergic agonists may present with the classic opioid toxic syndrome (Chaps. 3, 38, and 63) that is predominated by miosis and depression of the central nervous system and respiratory drive. Although this patient has many features consistent with that toxic syndrome, the normal oxygen saturation on room air, normal end-tidal CO₂, and failure to respond to naloxone largely exclude the diagnosis of an opioid. Also, most other etiologies for hypotension and bradycardia will decrease the mental status except for calcium channel blockers, which tend to preserve the level of consciousness.

An ECG should subsequently be evaluated (Fig. CS4–1). Although all of the etiologies listed in Table CS4–1 can present with sinus bradycardia, certain features may be suggestive of the etiology. When bradycardia is associated with traditional Class I antidysrhythmics, the QRS complex is usually significantly widened as a result of sodium channel blockade (Chap. 64). Patients who take cardioactive steroids often have underlying atrial fibrillation or demonstrate a digoxin effect (Fig. 65–2) or have ventricular premature beats, high degrees of atrioventricular blockade, or delayed after depolarizations on their ECGs (Chaps. 16 and 65). Finally, although a prolongation of the QT interval is nonspecific, it is expected with Class IA and IC antidysrhythmics and some opioids, most notably methadone.

FIGURE CS4–1. Electrocardiogram on presentation showing profound sinus bradycardia with a heart rate of 36 beats/min. The axis is normal, as are the PR interval of 120 msec and the QRS duration of 80 msec. The QT interval is slightly prolonged at 510 msec and there is no evidence of ischemia or infarction.

Rapid laboratory testing may also be of some utility. With acute toxicity from cardioactive steroids, the serum potassium concentration rises, and this increase has prognostic implications ([Chap. 65](#)). Less dramatic rises occur with β -adrenergic antagonist overdose but have unclear prognostic value. This patient's serum potassium was 5.2 mEq/L. β -Adrenergic antagonists also tend to cause hypoglycemia; in contradistinction hyperglycemia while not only common with calcium channel blockers, has prognostic implications.

Treatment A clinical decision was made to forgo attempts at gastrointestinal decontamination given the patient's mental status. She was given a second liter of 0.9% sodium chloride intravenously, and the decision was made to start with glucagon for a presumed β -adrenergic antagonist overdose. This diagnosis was suspected given the history of migraines, the ECG, the serum potassium concentration, and the blood glucose concentration. After 3 mg of glucagon IV, the patient's blood pressure rose to 102/62 mm Hg with a pulse of 60 beats/min, and this dose was repeated in 15 minutes when her blood pressure fell again (*Antidotes in Depth: A18*). Her anion gap was normal, and both APAP and ethanol concentrations were negative. By the next day, she was awake, and her vital signs remained normal. During a subsequent psychiatric evaluation, she admitted to taking an unspecified amount of propranolol. She was voluntarily admitted for psychiatric care.

60 ANTITHROMBOTICS

Betty C. Chen and Mark Su

HISTORY AND EPIDEMIOLOGY

Antithrombotics have numerous clinical applications, including in the treatment of coronary artery disease, cerebrovascular events, hypercoagulable states, deep venous thrombosis, and pulmonary embolism. The antithrombotics are a diverse group of xenobiotics that are widely studied and constantly in the process of therapeutic evolution.

The origins and discovery of antithrombotics are extraordinary.^{4,22,119,207} The discovery of modern-day oral anticoagulants originated following investigations of a hemorrhagic disorder in Wisconsin cattle in the early 20th century that resulted from the ingestion of spoiled sweet clover silage. The hemorrhagic agent, eventually identified as bishydroxycoumarin, would be the precursor to its synthetic congener warfarin (named after the Wisconsin Alumni Research Foundation). Warfarin was rapidly marketed as both a medicine and a rodenticide. “Superwarfarins” were subsequently developed for the increasing rat population that had developed genetic resistance to warfarin.

The origins of the anticoagulant heparin are equally fascinating. A medical student initially attempting to study ether soluble procoagulants derived from porcine intestines serendipitously found that, over time, these apparent “procoagulants” actually prevented normal blood coagulation. The phospholipid anticoagulant responsible for this effect would later be identified as a variant form of heparin. Shortly thereafter, the water-soluble mucopolysaccharide termed heparin (because of its abundance in the liver) was discovered. Unfractionated heparin is a mixture of polysaccharide chains with varying molecular weights. Following the identification of the active pentasaccharide segment of heparin in the 1970s, multiple low molecular-weight heparins were isolated and synthetic forms were created.

Hirudin, a 65 amino acid polypeptide, was produced by the salivary glands of the medicinal leech (*Hirudo medicinalis*).²⁵⁶ Antistasin and antistasinlike proteins are naturally secreted by the Mexican leech, *Haementeria officinalis*, and the earthworm.^{82,289} These xenobiotics have not been used therapeutically; however, they inspired the development of the synthetic factor inhibitors, such as direct thrombin inhibitors and factor Xa inhibitors.

In the late 19th century, human urine was noted to have proteolytic activity with specificity for fibrin. A substance found to be an activator of endogenous plasminogen leading to the consumption of fibrin, fibrinogen, and other coagulation proteins was isolated and purified and given the name urokinase. Streptokinase, a protein produced by β -hemolytic streptococci, tissue plasminogen activator (t-PA), and other synthetic thrombolytics were later discovered. Although known to exist for many years, anicrod, a purified derivative of Malayan pit viper, only recently gained therapeutic attention as a naturally occurring antithrombotic.

In the early 20th century, antithrombotic properties of aspirin were noted in anecdotal reports of patients having a predisposition to bleeding while taking aspirin. Clinicians also noted lower rates of myocardial infarction, and studies to elucidate the effects of aspirin on coagulation soon followed with further research exposing the role of platelet aggregation in thrombosis.²⁰¹ These discoveries led to the development of the antiplatelet xenobiotics.

The diversity of these antithrombotics has led to ever-increasing use in many fields of medicine. Although warfarin is the most common oral anticoagulant in use today because of its utility in patients with cerebrovascular disease, cardiac dysrhythmias, and thromboembolic disease, the emergence of newly developed oral antithrombotics has changed the landscape of modern medicine. During the period from 2009 to 2011, the total number of cases of reported antithrombotic exposures to the American Association of Poison Control Centers was 17,622 with 16 deaths ([Chap. 136](#)). Throughout this time, there was a general trend toward an increasing number of reports. In 2011, dabigatran and warfarin led the US Food and Drug Administration (FDA) Safety Information and Adverse Event Reporting Program’s list of adverse drug events, with 3781 reports of serious adverse events associated with dabigatran, including 542 patient deaths. In comparison, warfarin alone accounted for 1106 reports with 72 deaths.²⁰⁴

PHYSIOLOGY

Balance between Coagulation and Anticoagulation

An understanding of the normal function of the coagulation pathways is essential to appreciate the etiology of a

coagulopathy. This section summarizes the critical steps of the coagulation cascade. For additional details, the reader is referred to [Chap. 22](#) and several reviews.^{104,202,206,238}

Coagulation consists of a series of events that prevent blood loss and assist in the restoration of blood vessel integrity. Although the traditional understanding of the events that occur in the coagulation cascade,^{71,184} as discussed below, adequately describe *in vitro* events, the current understanding emphasizes some distinct differences that occur *in vivo*.^{104,206,238} Despite these differences, an understanding of the traditional model is most useful for interpreting the results of diagnostic tests of coagulation.

Within the cascade, coagulation factors exist as inert precursors and are transformed into enzymes when activated. Activation of the cascade occurs through one of two distinct pathways, the intrinsic and extrinsic systems (Fig. 60–1).^{71,184} Once activated, these enzymes catalyze a series of reactions that ultimately converge to generate thrombin with the subsequent formation of a fibrin clot.

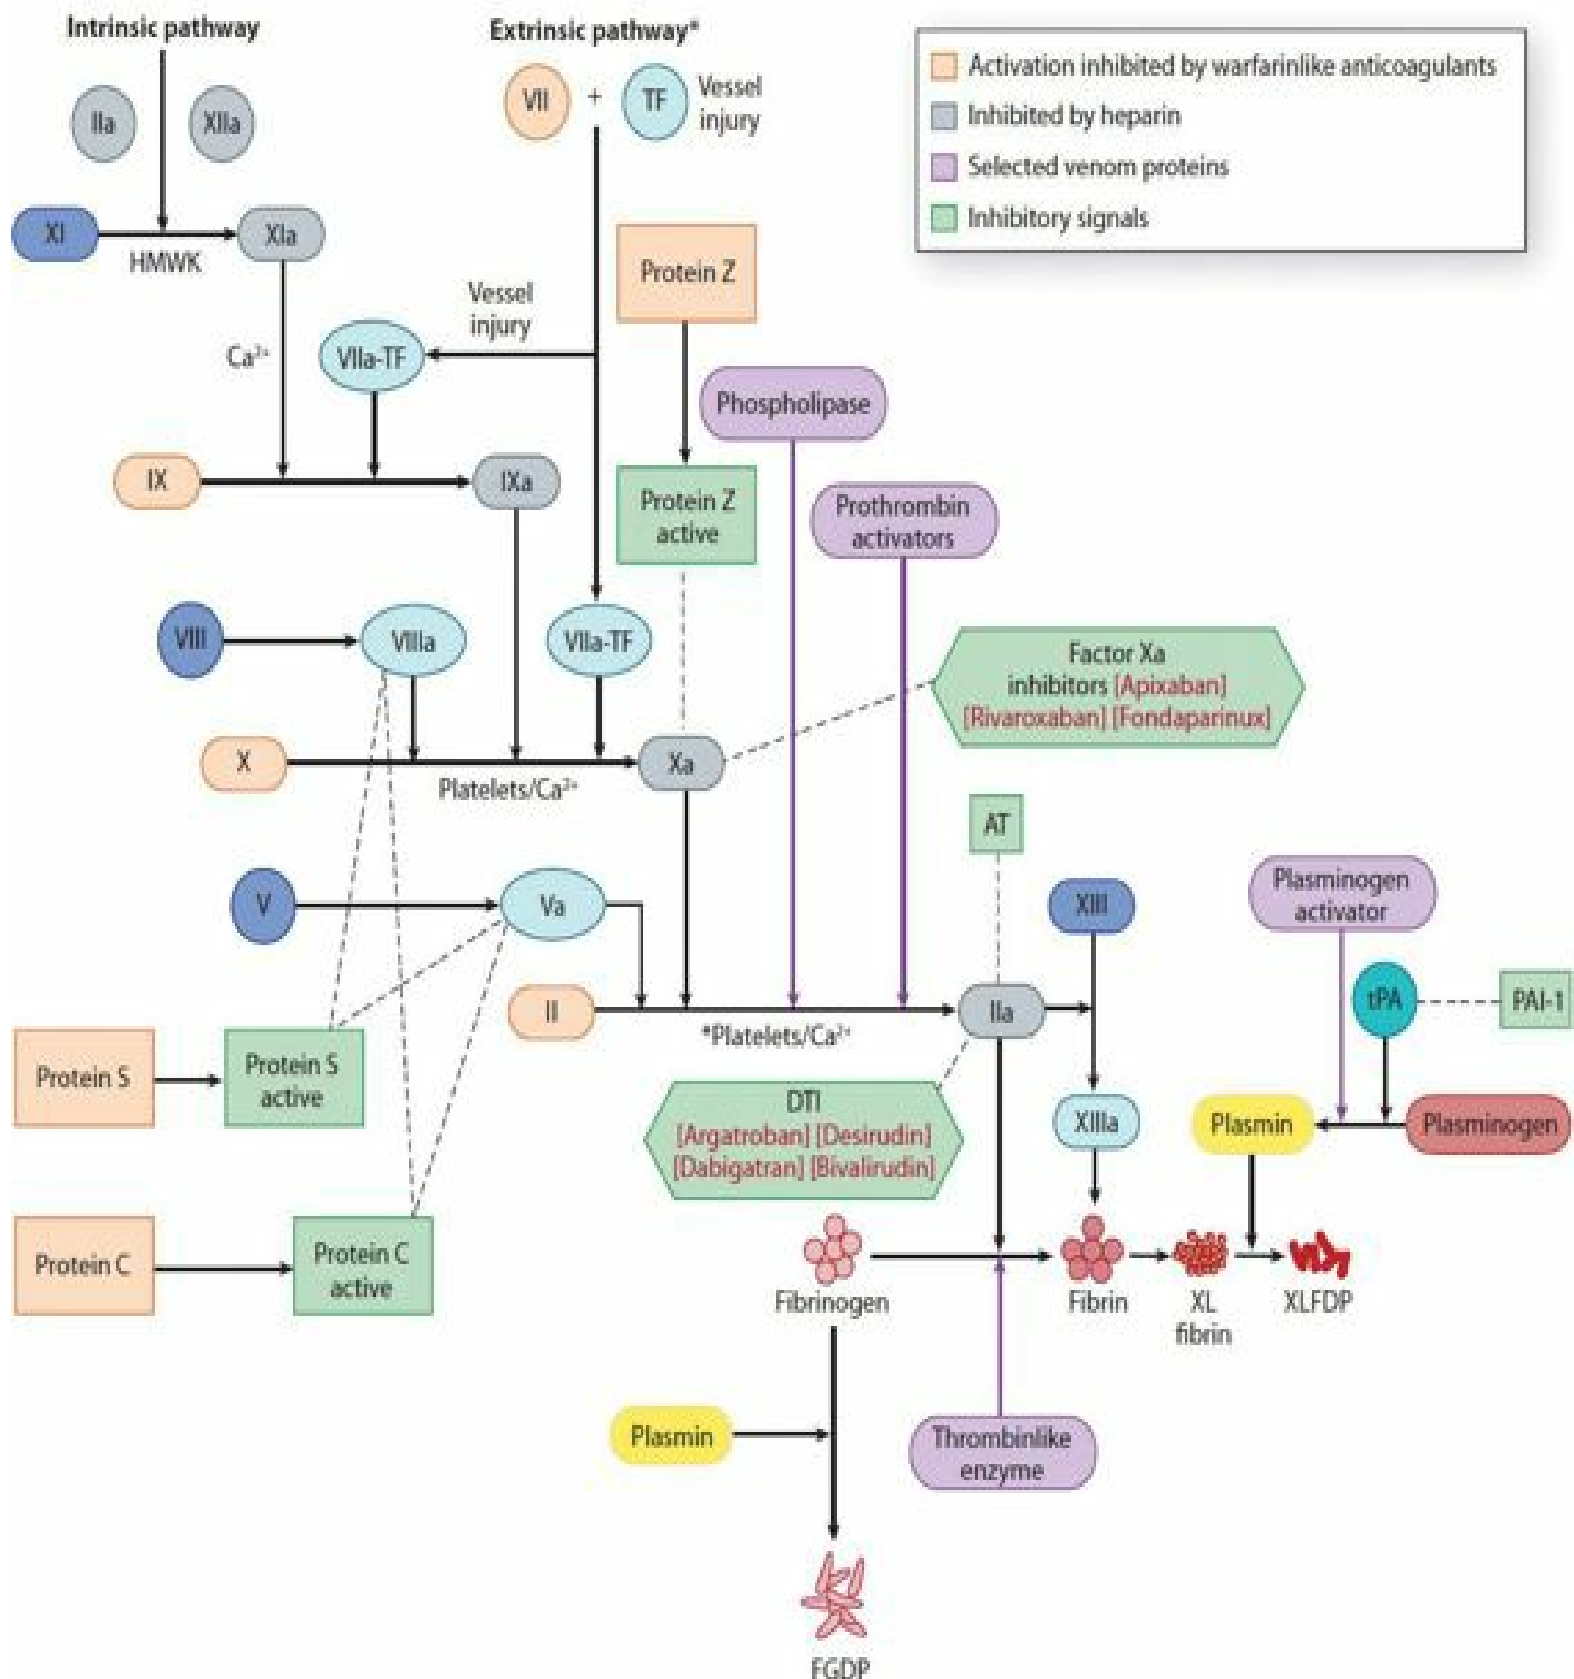

FIGURE 60–1. A schematic overview of the coagulation, platelet activation, and fibrinolytic pathways indicating where phospholipids on the platelet surface interact with the coagulation pathway intermediates. Arrows are not shown from platelets to phospholipids involved in the tissue factor VIIa and the factor IX to VIIIa interactions to avoid confusion. Interactions of selected venom proteins are indicated in the purple boxes. The diagram is not complete with reference to the multiple sites of interaction of the serine protease inhibitors (SERPINs) to avoid overcrowding. Dashed lines indicate inhibitory effects. *Refer to Figs. 60–4 and 60–5 for platelet activation pathway. DTI = direct thrombin inhibitor; FDP = fibrin degradation products; FGDP = fibrinogen degradation products; HMWK = high molecular weight kininogen; TF = tissue factor; XL = cross-linked.

The intrinsic pathway is activated by the complexation of factor XII (Hageman factor) with high-molecular-weight kininogen (HMWK) and prekallikrein, or vascular subendothelial collagen. This results in sequential activation of factor XII, active kallikrein, active factors IX to XI, and prothrombin (factor II) (Fig. 60–1). Prothrombin is converted to thrombin in the presence of factor V, calcium, and phospholipid. The integrity of this system is usually evaluated by determining the partial thromboplastin time (PTT).

In the extrinsic or tissue factor dependent pathway, a complex is formed between factor VII, calcium, and tissue factor, which is released following injury. A calcium and lipid dependent complex is then created between factors VII and X. The factor VII–X complex subsequently converts prothrombin to thrombin, which promotes the formation of fibrin from fibrinogen (Fig. 60–1). The integrity of this pathway is usually assessed by determining the prothrombin time (PT or international normalized ratio {INR}). The distinction between PT and INR is discussed in Chap. 22.

Activation of factor X provides the important link between the intrinsic and extrinsic coagulation pathways. Additional evidence that tissue factors can activate both factors IX and X suggests that there are more interrelations between the two pathways.²¹⁸ Furthermore, cell surfaces facilitate the process of clotting. Platelets are also known to interact with proteins of the coagulation cascade through surface receptors for factors V, VIII, IX, and X.^{109,188,263} As a final step, factor XIII assists in the cross-linking of fibrin to form a stable thrombus.

Antithrombin (AT), and proteins C, S, and Z serve as inhibitors, maintaining the homeostasis that is required to prevent spontaneous clotting and keep blood fluid. Protein C, when aided by protein S, inactivates two plasma factors, V and VIII.^{34,56,104} Protein Z is a glycoprotein molecule that forms a complex with the protein Z dependent protease inhibitor (ZPI) which, in turn, inhibits the activated factor X (Xa).²⁹⁷ AT complexes with all the serine protease coagulation factors (factor Xa, factor IXa, and contact factors, including XIIa, kallikrein, and HMWK), except factor VII.^{34,104,238}

Thrombolytics such as streptokinase, urokinase, anistreplase, and recombinant tissue plasminogen activator (rt-PA) enhance the normal processes that lead to clot degradation.²⁰⁶

Thrombosis is initiated when exposed endothelium or released tissue factors lead to platelet adherence and aggregation, the formation of thrombin, and cross-linking of fibrinogen to form fibrin strands.^{104,206,238} This results in a hemostatic plug or thrombus formation. Thrombus formation, in turn, leads to generation of plasmin from plasminogen, which causes fibrinolysis and eventual dissolution of the hemostatic plug.^{57,58} Thus the fibrinolytic system may be thought of as a natural balance against unregulated coagulation. Thrombolytic therapy increases fibrinolytic activity by accelerating the conversion of plasminogen to plasmin, which actively degrades fibrin.^{57,58} Following the administration of thrombolytics, a drug-induced coagulopathy ensues, and fibrin degradation products are elevated secondary to the rapid turnover of clot.

DEVELOPMENT OF COAGULOPATHY

Impaired coagulation results from decreased production or enhanced consumption of coagulation factors, the presence of inhibitors of coagulation, activation of the fibrinolytic system, or abnormalities in platelet number or function. Platelets are involved in the initial phases of clotting following blood vessel injury by assisting in the formation of the fibrin plug.

Decreased production of coagulation factors results from congenital and acquired etiologies. Although congenital disorders of factor VIII (hemophilia), factor IX (Christmas factor), factor XI, and factor XII (Hageman factor) are all reported, their overall incidence is still quite low. Clinical conditions that result in acquired factor deficiencies are much more common and result from either a decrease in synthesis or activation. Factors II, V, VII, and X are entirely synthesized in the liver,^{104,206,238} making hepatic dysfunction a common cause of acquired coagulopathy. In addition, factors II, VII, IX, and X also require postsynthetic modification by an enzyme that uses vitamin K as a cofactor,^{273,278,279} such that vitamin K deficiency (from malnutrition, changes in gut flora secondary to xenobiotics, or malabsorption), or inhibition of vitamin K cycling (from warfarin) are all capable of impairing coagulation.

Excessive consumption of coagulation factors usually results from massive activation of the coagulation cascade. Massive activation occurs during severe bleeding or disseminated intravascular coagulation. The latter results from infection, such as sepsis, and from conditions that introduce tissue factor into the blood, such as neoplasms, snake envenomations, stagnant blood flow, diffuse endothelial injury secondary to hyperthermia, ruptured aortic aneurysm, or

aortic dissection. The hallmark of a consumptive coagulopathy is a depressed concentration of fibrinogen with an elevation of fibrin degradation products. This combination suggests the rapid turnover of fibrin in the coagulation process. In the other coagulopathic conditions, the failure to activate the coagulation cascade is associated with normal or high fibrin concentrations and low fibrin degradation products because of limited clot formation.

Hypothermia is a well known cause of disseminated intravascular coagulation leading to death.²⁸⁴ Canine studies show decreased fibrinogen, factor II, and factor VII concentrations when cooled to 68°F (20°C) while a simultaneous rise in factor V concentration occurs.¹⁴⁰ In vitro studies show increased coagulation time, clot formation time, and maximum clot strength in hypothermic whole blood samples from healthy volunteers.^{80,242} In addition, thrombocytopenia occurs secondary to sequestration in the spleen, liver, and splanchnic circulation.^{236,275} Infants with hypothermia have an increased risk for intracranial and pulmonary hemorrhage.⁴⁷

Inhibitors of the coagulation cascade (circulating anticoagulants) are of two types: immunoglobulins to coagulation factors or antibodies to phospholipid membrane surfaces. Immunoglobulins may occur without obvious cause, be part of a systemic autoimmune disorder, or be the result of repeated transfusions with exogenous factors (as occurs in patients with hemophilia).^{125,167,257} Antibodies to factors V, VII to XI, and XIII are described.^{26,257} The clinical syndromes associated with antibody inhibitors are similar to those associated with deficiencies of the particular coagulation factors involved. Antiphospholipid antibodies are directed against phospholipid membrane surfaces and β_2 -glycoprotein I, also known as apolipoprotein H. This protein is essential in preventing hemostasis by inhibiting ADP-induced platelet aggregation, inhibiting activation of the intrinsic pathway of the coagulation cascade, and inhibiting both platelet-mediated factor Xa and factor VII activation. Therefore, destroying β_2 -glycoprotein I creates a prothrombotic clinical status.^{252,253,260} Paradoxically, this antibody creates a prolonged PTT because the antibody also binds to most phospholipid containing PTT reagents. This reduction in amount of active reagent results in a falsely elevated PTT.^{125,167}

GENERAL MANAGEMENT

Gastrointestinal decontamination should be performed on patients who are believed to have potentially significant life threatening ingestions unless they already present with significant bleeding. For patients who present after a few hours of ingestion, gastric emptying is not indicated (**Chap. 8**). Although convincing data on the efficacy of either single- or multiple-dose activated charcoal (AC; possible enterohepatic circulation) are lacking, a single dose of AC seems appropriate unless it is contraindicated. Oral cholestyramine can also be used to enhance warfarin elimination,²³⁵ but no studies are available that compare these two therapies or evaluate the role of combined AC and cholestyramine therapy. In addition to general supportive measures, the patient should be placed in a supervised medical and psychiatric environment that offers protection against external or self-induced trauma and permits observation for the onset of coagulopathy.

Blood transfusion is required for any patient with a history of blood loss or active bleeding who is hemodynamically unstable, has impaired oxygen transport, or is expected to become unstable. Although a transfusion of packed red blood cells is ideal for replacing lost blood, it cannot correct a coagulopathy, and thus patients will continue to bleed. Whole blood contains both the cellular elements and necessary coagulation factors to reverse the coagulopathy. Transfusion of whole blood may be considered in severe cases because whole blood contains many components, including platelets, white blood cells, and non-vitamin K-dependent factors.

VITAMIN K ANTAGONISTS

Warfarin and “Warfarinlike” Anticoagulants

The vitamin K antagonist (VKA) anticoagulants can be divided into two groups: (a) hydroxycoumarins, including warfarin (commonly called by its trade name Coumadin), difenacoum, coumafuryl, fumasol, prolin, ethyl biscoumacetate, phenprocoumon, dicumarol, bishydroxycoumarin, and acenocoumarin; and (b) indanediones, including chlorophacinone, diphacinone, diphenadione, phenindione, and anisindione. Regardless of the classification, their mechanism of action involves inhibition of the vitamin K cycle. Vitamin K is a cofactor in the postribosomal synthesis of clotting factors II, VII, IX, and X (**Fig. 60–2**). The vitamin K-sensitive enzymatic step that occurs in the liver involves the γ -carboxylation of 10 or more glutamic acid residues at the amino terminal end of the precursor proteins, to form a unique amino acid γ -carboxyglutamate.^{81,273,278,279} These amino acids chelate calcium in vivo, which allows the binding of the four vitamin K-dependent clotting factors to phospholipid membranes during activation of the coagulation cascade.³¹⁷

FIGURE 60–2. The vitamin K cycle. Dotted lines represent pathways that can be blocked with warfarin and warfarinlike anticoagulants. The aliphatic side chain (R) of vitamin K is shown below the metabolic pathway. VKORC1 = vitamin K reductase complex 1.

Vitamin K is inactive until it is reduced from its quinone form to a quinol (or hydroquinone) form in hepatic microsomes. This reduction of vitamin K must precede the carboxylation of the precursor factors. The carboxylation activity is coupled to an epoxidase activity for vitamin K, whereby vitamin K is oxidized simultaneously to vitamin K 2,3-epoxide (Fig. 60–2).^{278,316} This inactive form of the vitamin is converted back to the active form by two successive reductions.^{81,186,220,311} In the first step, an epoxide reductase (known as vitamin K 2,3-epoxide reductase) uses reduced nicotinamide adenine dinucleotide (NADH) as a cofactor to convert vitamin K 2,3-epoxide to a quinone form.^{214,215,278} Subsequently, the quinone is reduced to the active vitamin K quinol form (Antidotes in Depth: A15).

Warfarin is a racemic mixture of R warfarin and S warfarin enantiomers. In humans, S warfarin is approximately 2.7 to 3.8 times more potent than R warfarin.³⁷ Warfarin and all warfarinlike compounds inhibit the activity of vitamin K 2,3-epoxide reductase, as can be demonstrated by the observation of elevated concentrations of vitamin K 2,3-epoxide.^{53,320} Additional evidence suggests that vitamin K quinone reductase is also inhibited by warfarin and its related compounds (Fig. 60–2).^{81,95} This reduction in the cyclic activation of vitamin K subsequently inhibits the formation of activated clotting factors.

Pharmacology of Vitamin K Antagonists

Oral warfarin is well absorbed, and peak serum concentrations occur approximately 3 hours after administration.²⁷⁷ Because only the free warfarin is therapeutically active, concurrent administration of xenobiotics that alter the concentration of free warfarin, either by competing for binding to albumin or by inhibiting warfarin metabolism, may markedly influence the anticoagulant effect.^{17,100,277} The pharmacologic response to warfarin is a polygenic trait with approximately 30 genes contributing to its therapeutic effects.¹⁵³ The reader is referred to a review of xenobiotics and foods that potentiate warfarin's effects.³¹⁴ Although vitamin K regeneration is altered almost immediately, the anticoagulant effect of warfarin and other warfarin-like anticoagulants is delayed until the existing stores of vitamin K are depleted and

the active coagulation factors are removed from circulation. Because vitamin K turnover is rapid, this effect is largely dependent on factor half-life ($t_{1/2}$), with factor VII ($t_{1/2} \sim 5$ hours) depleted most rapidly.¹⁰⁰ For a prolongation of the INR to occur, factor concentrations must fall to approximately 25% to 30% of normal values.⁵⁵ Assuming complete inhibition of the vitamin K cycle, this suggests that most patients require at least 15 hours (three factor VII half-lives) before the effect of warfarin is evident on the INR.⁹⁷ In fact, since complete inhibition does not occur, the onset of coagulation is delayed even further.

Because the half-life of warfarin in humans is 35 hours, its duration of action may be as long as 5 days.^{36,277} On average, it takes approximately 6 days of warfarin administration to reach a steady-state anticoagulant effect.

R warfarin is metabolized by enzymes CYP1A2 and CYP3A4, and S warfarin is metabolized by CYP2C9 of the hepatic microsomal P450 enzyme system. R warfarin is metabolized by side-chain reduction to secondary alcohols that are subsequently excreted by the kidney, whereas S warfarin is metabolized by hydroxylation to 7-hydroxy warfarin, which is excreted into the bile.²⁷⁷ The elimination of S warfarin is more rapid than that of R warfarin.³⁷

Dosing of warfarin and other VKAs is problematic in many patients. In one study, genetic polymorphisms of the vitamin K epoxide reductase complex 1 (VKORC1) and CYP2C9 genes appear to be the strongest predictors of interindividual variability in the anticoagulant effect of warfarin.¹⁵³ Pharmacogenomic research with complex xenobiotics, such as warfarin, may improve the treatment of patients and predict or prevent interactions with other xenobiotics. While the FDA has approved a commercially available test to identify variants within these genes,¹⁵¹ current guidelines do not advocate genetic testing to guide VKA dosing.¹¹⁷

Within the coumarin group are two 4-hydroxycoumarin derivatives, difenacoum and brodifacoum, that differ from warfarin by their longer, higher molecular weight polycyclic hydrocarbon side chains. Together with chlorophacinone, an indandione derivative, they are known as superwarfarins or long-acting VKAs.

Long-acting VKAs were designed to be effective rodenticides in warfarin-resistant rodents.¹⁸³ Their mechanism of action is identical to that of the traditional warfarinlike anticoagulants, as demonstrated by increased concentrations of vitamin K 2,3-epoxide after administration.^{35,38,41,168,220} The ability of these xenobiotics to perform as superior rodenticides is attributed to their high lipid solubility and concentration in the liver.^{168,183,220} They also may saturate hepatic enzymes at very low concentrations, as demonstrated by zero-order elimination following overdose.⁴¹ These factors make them about 100 times more potent than warfarin on a molar basis.^{168,183,220} In addition, they have a longer duration of action than the traditional warfarins.^{168,183,220} For example, to obtain 100% lethality in a mouse, more than 21 days of feeding with a warfarin-containing rodenticide (0.025% anticoagulant by weight of bait) is required.¹⁸³ Similar efficacy can be achieved with a single ingestion of brodifacoum (0.005% anticoagulant by weight of bait).¹⁸³ Furthermore, more concentrated liquid formulations, such as brodifacoum (0.5% anticoagulant), are available through illegal vendors and have been implicated in prolonged coagulopathy.¹⁰⁷ It should also be noted that although ingestion of these xenobiotics is the most common route of exposure and subsequent cause of toxicity, dermal absorption of liquid preparations can occur, also resulting in a coagulopathy.²⁶⁸

Clinical Manifestations

Although intentional ingestions of warfarin-containing products are uncommon, adverse drug events resulting in excessive anticoagulation and bleeding frequently occur. The risk of bleeding during VKA therapy depends on a myriad of factors, including the intensity of anticoagulation, patient characteristics, and comorbid conditions. Clearly, the most serious complication of excessive anticoagulation is intracranial bleeding, which is reported to occur in as many as 2% of patients on long term therapy, which is an 8 to 10 fold increase in risk when compared to patients who are not anticoagulated.^{99,100,322} Overall risk of major bleeding in patients can be estimated using tools such as the Hypertension, Abnormal Renal/Liver Function, Stroke, Bleeding History or Predisposition, Labile INR, Elderly, Drugs/Alcohol Concomitantly (HAS-BLED) score, which has been prospectively validated in patients with atrial fibrillation.^{179,226} Bleeding can range between 1 and 12.5 episodes per 100 patient-years, with a higher risk in patients with multiple risk factors.²²⁶ Another study showed that patients over the age of 80 have a cumulative incidence of major bleeding at 13.1 per 100 person-years with major bleeding defined as bleeding at serious sites (eg, intracranial, retroperitoneal, intraspinal, or pericardial) or bleeding that results in blood transfusion or death. Patients between the ages of 65 and 80 have a lower risk of 4.7 major episodes of bleeding per 100 person-years.¹³⁵ Major bleeding complications are associated with a fatality rate as high as 77%.¹⁹¹ A recent study of patients with intracranial bleeding found that decreased level of consciousness and increased size of hematoma were predictors of poor prognosis.³³¹ Somewhat surprisingly, the degree of INR elevation was not associated with worse outcome.³³¹

Many cases of intentional overdose of long-acting VKAs in humans are described in the literature. The clinical courses of these patients are characterized by a severe coagulopathy that may last weeks to months, often accompanied by consequential blood loss. Most patients do not seek medical care until bruising or bleeding is evident,^{14,41,42,94,129,152} which

often occurs many days after ingestion. The most common sites of bleeding are the gastrointestinal and genitourinary tracts. In one study describing 12 patients with surreptitious ingestion of oral anticoagulants, nine were health care professionals.²¹⁵ These patients presented with bruising, hematuria, hematochezia, and menorrhagia. Bleeding into the neck with resultant airway compromise is a rare but life-threatening complication that has occurred.³¹

Patients with unintentional ingestions must be distinguished from those with intentional ingestions, because the former demonstrate a low likelihood of developing a coagulopathy and have rare morbidity or mortality. Most patients (usually children) are entirely asymptomatic and have a normal coagulation profile following an acute unintentional exposure. Typical warfarinlike rodenticides contain only small concentrations of anticoagulant, 0.005% (or 5 mg of brodifacoum per 100 g of product). A 10 kg child would require an initial dose of 10 g of rodenticide (8 pellets, each of which is approximately 25 mm in size). These quantities are far greater than those that occur in typical “tastes.” Thus, single small unintentional ingestions of warfarin-containing rodenticides pose a minimal threat to normal patients.¹⁴⁷ Prolongation of the INR is unlikely with a single small ingestion of a long-acting VKA rodenticide. Clinically significant anticoagulation is even rarer. In a combined pediatric case series, prolongation of the INR occurred in only 8 of 142 children (5.6%) reported with single small ingestions of long-acting VKAs.^{21,146,147,266} Only one child in this group was reported to have “abnormal prolonged bleeding,” but this required no medical attention.²⁶⁶ In a single case report, a 36 month-old child developed a coagulopathy manifested by epistaxis and hematuria, with anticoagulation persisting for more than 100 days after a presumed, but unwitnessed, single unintentional ingestion of brodifacoum.²⁸⁵ Clinically significant coagulopathy can result, however, following small repeated ingestions. Two children reportedly became poisoned by repeated ingestions of a long-acting anticoagulant. One child presented with a neck hematoma that compromised his airway, and the other with a hemarthrosis.¹¹⁵ Similarly, a 7 year-old girl required multiple hospitalizations over a 20 month period following repeated unintentional ingestions of brodifacoum.²⁴ Finally, a 24 month-old child who presented with unexplained bruising and a PT greater than 125 seconds was the victim of brodifacoum poisoning secondary to Munchausen syndrome by proxy.¹⁰

Laboratory Assessment

Although warfarin concentrations may be useful to confirm the diagnosis in unknown cases and to study drug kinetics,^{118,212} the routine use of simple and inexpensive measures such as INR determination seems more appropriate (Table 60–1). When blood loss is evident, serial determinations of hemoglobin concentration are indicated.

TABLE 60–1. Antithrombotics: Laboratory Testing, Antidotes, and Treatment Strategies

	Laboratory Testing	Antidotes and Treatment Strategies
Antiplatelet Agents Cyclooxygenase inhibitors Phosphodiesterase inhibitors Adenosine uptake inhibitors Adenosine diphosphate receptor inhibitors Glycoprotein IIb/IIIa inhibitors	Bleeding time prolonged; platelet function assays abnormal	Desmopressin 0.3 µg/kg IV for life-threatening bleeding; platelet administration is controversial
Antithrombin Agents Unfractionated heparin	PTT prolonged; TT abnormal; ACT elevated; fibrinogen normal; anti-factor Xa activity decreased	1 mg protamine per 100 units of heparin. In overdose, if unknown quantity of heparin administered, treat based on ACT*, or empirically with 25–50 mg ACT < 150 sec: no protamine needed ACT 200–300 sec: 0.6 mg/kg protamine ACT 300–400 sec: 1.2 mg/kg protamine
Low-molecular-weight heparin (eg, enoxaparin, dalteparin)	Anti-factor Xa activity decreased; PTT is insensitive	For partial reversal, 1 mg protamine per 100 anti-factor Xa units (or 1 mg of enoxaparin) given in the last 8 hours. May administer an additional 0.5 mg protamine per 100 anti-factor Xa units if bleeding continues
Direct Thrombin Inhibitors Dabigatran Bivalirudin Argatroban	PTT prolonged; TT prolonged; ECT prolonged; anti-factor Xa activity elevated (at low concentrations, PT and PTT may be normal); dTT prolonged ^{†‡§}	Activated charcoal in acute overdose PCC administration with up to 100 units/kg in repeated 50 units/kg doses as needed. If bleeding continues 30 minutes after PCC, give FEIBA. [¶] Consider hemodialysis FFP 15 mL/kg
Factor Xa Inhibitors Rivaroxaban Apixaban	PT and PTT normal or prolonged (can vary with reagents); anti-factor Xa elevated; specific modified chromogenic antifactor Xa [¶]	Activated charcoal in acute overdose only PCC administration with up to 50 units/kg in repeated 25 units/kg doses as needed
Fibrinolytics	PT and PTT prolonged; TT abnormal; fibrinogen abnormal	Cryoprecipitate Factor replacement with 15 mL/kg of FFP or 50 units/kg of PCC For life-threatening bleeding, consider tranexamic acid at 1 g intravenously over 10 minutes, followed by 1 g over 8 hours. If tranexamic acid is unavailable, IV aminocaproic acid can be given as a loading dose of 5 g over 1 hour, followed by an infusion at 1 g/h for 23 hours. Stop infusion if bleeding ceases.
Pentasaccharides Fondaparinux	Fondaparinux-specific anti-Xa assay PTT is insensitive	PCC administration with up to 50 units/kg in repeated 25 units/kg doses as needed.
Vitamin K Antagonists Warfarin	Early (PT prolonged; PTT normal) Late (PT and PTT prolonged; TT and fibrinogen normal)	Vitamin K Factor replacement (FFP or PCC) See Table 40–7 for detailed management recommendations

*May need to repeat in 2–4 hours due to potential heparin rebound. †Size of ACT is only validated in the operative setting following cardiopulmonary bypass. ‡In patients with a history of heparin-induced thrombocytopenia, avoid PCC (except proline) and use FEIBA or rFVIIa. §No readily available method to assess extent of anticoagulation at this time.

ACT = activated clotting time; ECT = ecarin clotting time; FFP = fresh frozen plasma; PCC = prothrombin complex concentrate; PT = prothrombin time; PTT = partial thromboplastin time; TT = thrombin time; FEIBA = factor eight inhibitor bypassing activity.

For patients with an acute and significant long acting VKA overdose, daily INR evaluations for 2 days should be adequate to identify most patients at risk for coagulopathy. Earlier detection through direct coagulation factor analysis may be preferred,^{118,129} and concentrations of long acting VKAs can now be measured, although they are usually only performed in reference laboratories.^{157,212} Children with possibly significant exposures should be followed up with at least a single INR at least 48 hours after the exposure. Despite the fact that significant toxicity from long acting VKAs is rare, it should be recognized that the reported benign courses of exposures in children may be misleading. Multiple retrospective studies suggest that children with unintentional acute exposures do not require any follow-up coagulation studies.^{205,208,222,258} However, this conclusion and approach to management may be an unjustified attempt to decrease the cost of “unnecessary” coagulation studies. There are clearly insufficient data to justify this conclusion, as many of these “exposed” children were never documented to have ingested long-acting VKAs (Chap. 136). We recommend that clinicians continue to manage these children as possibly significant exposures and that all children be followed up with at least a single INR at a minimum of 2 days after the exposure. A baseline INR is usually unnecessary but may be performed if there is a suspicion of an antecedent ingestion. A baseline INR is also helpful when chronic exposure is suspected.

Treatment of Vitamin K Antagonist Induced Coagulopathy

Life threatening bleeding secondary to VKA toxicity should be immediately reversed with factor replacement, followed by vitamin K₁ (Table 60–1). The American College of Chest Physicians recommends factor replacement with four-factor prothrombin complex concentrate (PCC) as a first-line treatment.¹³⁰ While four-factor PCC has recently become available in the United States, three-factor PCC was more commonly stocked by hospitals. There are no trials that directly compare four-factor PCC against three-factor PCC. Both formulations contain concentrated factors II, VII, IX, X, C, and S. However, the factor VII concentration is significantly decreased to limit thrombosis potential in three-factor PCC. Most countries use traditional four-factor PCC, which contains factor VII in its formulation. Most forms of PCC, contain small amounts of heparin. These heparin-containing PCCs are contraindicated in patients with heparin-induced thrombocytopenia (HIT) and heparin-induced thrombocytopenia and thrombosis syndrome (HITT). In those cases, factor eight inhibitor bypassing activity (FEIBA), an activated prothrombin complex concentrate (aPCC), should be used. FEIBA does not contain heparin, and is, therefore, acceptable to use in patients with HIT or HITT. Despite its increased cost, the rationale for using PCC instead of fresh-frozen plasma (FFP) includes less risk of infection transmission.¹³⁰ In addition, small-volume factor replacement may be preferable in patients at risk of volume overload, such as patients with heart failure, chronic kidney disease (CKD), or intracranial bleeding.¹ Unfortunately, there are only a few studies comparing PCC with FFP in reversing coagulopathy. These studies show that PCC safely produces complete INR reversal faster than FFP with more consistent factor IX replacement.^{74,143,187} However, unequal factor replacement in these small studies favors more factor replacement in patients receiving PCC,²⁴⁷ and the use of four-factor PCC currently limits the generalizability of these studies to clinical practice in the United States. FFP is rich in active vitamin K–dependent coagulation factors and will reverse oral anticoagulant-induced coagulopathy in most patients. In general, approximately 15 mL/kg of FFP should be adequate to reverse any VKA-induced coagulopathy.⁶⁸ However, the specific factor quantities and volume of each unit may be varied, leading to an unpredictable response.¹⁸⁷ In addition, delay to FFP administration may be accentuated by requirements for blood type matching and thawing.

rfVIIa is approved for patients with hemophilia or various factor inhibitors and has been successfully used to reverse VKA toxicity. The safety of off-label rFVIIa to reverse VKA coagulopathy is unclear. Preliminary data using rFVIIa suggested its utility for bleeding secondary to warfarin induced excessive anticoagulation, and a case series showing beneficial effects in four patients with long acting VKA toxicity.³³² However, adverse outcomes such as arterial thrombotic events may occur at higher than acceptable rates. Initial concerns for thromboembolic adverse events were raised when review of the FDA’s Adverse Event Reporting System database found that the majority of these complications arose in patients who received rFVIIa for off-label purposes. Cerebrovascular accident, acute myocardial infarction, pulmonary embolism, venous thrombosis, and clotted devices all occurred at higher rates in off-label applications.²¹³ The Factor Seven for Acute Hemorrhagic Stroke Trial (FAST) showed that arterial thromboembolic adverse events increased in a dose dependent fashion with the administration of rFVIIa.⁷⁹ A subsequent meta-analysis confirmed that an increased rate of arterial thrombosis occurs in patients who receive rFVIIa.¹⁷⁵ The risk of continued bleeding versus the benefit of rapid reversal of coagulopathy with rFVIIa is unknown, and further experience with rFVIIa is necessary to determine its safety and efficacy in anticoagulant-induced bleeding. It should also be noted that if rFVIIa is used, assays based on PT may be inaccurate and should be avoided when administering rFVIIa.¹⁴⁸

Treatment with vitamin K₁ takes several hours to activate enough factors to reverse the patient’s coagulopathy,^{187,221} and this delay may be potentially fatal. Repetitive, large doses of vitamin K₁ (on the order of 60 mg/d or greater) may be required in some patients.^{118,215} If complete reversal of INR prolongation occurs or is desirable (as in most cases of life-threatening bleeding), and the underlying medical condition of the patient still requires some degree of anticoagulation, the patient can then receive anticoagulation with heparin once the bleeding is controlled and clinical stability restored. Heparin

anticoagulation was used without apparent bleeding complications in 25% of patients in one cross-sectional study.³¹⁹

Vitamin K₁ is preferable over the other forms of vitamin K; the other forms are ineffective^{141,209,214,291} and are potentially toxic.¹² Other forms, such as vitamin K₃ (menadione) and vitamin K₄ (menadiol sodium diphosphate), can cause oxidative stress on neonatal erythrocytes and produce hemolysis, hyperbilirubinemia, and kernicterus. They are not available in the United States. Parenteral administration of vitamin K₁ (phytonadione) is traditionally preferred as initial therapy by many authors, but success can also be achieved with early oral therapy, especially when the coagulopathy is not severe.⁴¹ In most cases, the patient can be switched to oral vitamin K₁ for long-term care. Vitamin K₁ can be administered intramuscularly, subcutaneously, intradermally, or intravenously. Although intravenous therapy has the most rapid onset of action of all routes of delivery, its use as the sole therapeutic is still associated with a delay of several hours^{221,311} and carries the added risk of anaphylactoid reactions.²³⁷ The use of low doses and slow rate of administration reduces this risk²⁶¹ (Antidotes in Depth: A15). In cases where oral administration is undesirable, for example, with significant gastrointestinal bleeding, the subcutaneous route may be used, realizing that absorption may be erratic. Furthermore, if a patient is anticoagulated or overanticoagulated, administration of vitamin K₁ by the intramuscular route may result in a large hematoma. Caution should be exercised if this route of administration is chosen.

For patients with non-life-threatening bleeding, the clinician must consider whether anticoagulation is required for long-term care. In patients not requiring chronic anticoagulation, even small elevations of the INR may be treated with vitamin K₁ alone to prevent deterioration in coagulation status and reduce the risk of bleeding. Because most cases of warfarin-induced coagulopathy only last several days, there may be a rationale for prophylactic vitamin K₁ administration in known warfarin-like anticoagulant ingestions in patients not requiring anticoagulation. In contrast to ingestions of warfarin, prophylactic vitamin K₁ should not be given to asymptomatic patients with unintentional ingestions of long-acting warfarinlike anticoagulants because (a) if the patient develops a coagulopathy, it will last for weeks, and the one or two doses of vitamin K₁ given will not prevent complications; (b) a gradual decline in coagulation factors occurs over the first day of anticoagulation, so an individual would not be expected to develop a life-threatening coagulopathy in 1 or 2 days; and (c) after vitamin K₁ is administered, the onset of an INR abnormality will be delayed, which could impair the ability of the clinician to recognize a coagulation abnormality, possibly requiring the patient to undergo an unnecessarily prolonged observation period.

For patients requiring chronic anticoagulation, the American College of Chest Physicians has issued guidelines for the management of patients with elevated INRs (Table 60–2). Moreover, the use of a regression formula may assist in calculating the amount of oral vitamin K₁ necessary to partially correct the INR, without completely discontinuing the oral anticoagulant. Although this formula remains unvalidated, it may be useful prior to minor surgery or dental procedures in patients requiring chronic anticoagulation, while theoretically decreasing the likelihood of thromboembolism.^{67,315} It should also be noted that low-dose vitamin K may be safely administered to patients with mildly elevated INRs (4 to 10) to decrease the INR more rapidly; however, one study did not demonstrate decreased bleeding in the treatment group.⁶⁷ Furthermore, simply omitting warfarin doses may be adequate for the patient without active bleeding who has an INR between 4 and 9.⁶⁷

TABLE 60–2. Recommendations for Management of Elevated INRs or Bleeding in Patients Receiving Vitamin K Antagonists

<i>INR</i>	<i>Recommendations^a</i>
<4.5; no significant bleeding	Lower or omit the next dose of warfarin
≥4.5–10; no significant bleeding	Omit warfarin for the next one or two doses
>10; no evidence of bleeding	Give oral vitamin K ₁ (1–2.5 mg). If more rapid reversal is necessary, give oral vitamin K ₁ (≤5 mg) and wait 24 hours. Give additional vitamin K ₁ orally (1–2 mg) as needed
Serious bleeding at any INR concentration or life-threatening bleeding	Hold warfarin therapy and give FFP or PCC supplemented with vitamin K ₁ (5–10 mg by slow intravenous ^b infusion). Vitamin K ₁ administration may need to be repeated q12h

^aData from Reference 130. ^bIntravenous infusion of vitamin K₁ rarely may cause severe anaphylactoid reactions.

FFP = fresh frozen plasma; INR = international normalized ratio; PCC = prothrombin complex concentrate.

It is often unclear why patients with consistent therapeutic dosing have seemingly random elevations in their INR. A

case-control study identified the following risk factors associated with overanticoagulation from VKAs: previous medical history of increased INR, antibiotic therapy, fever, and concomitant use of amiodarone and proton pump inhibitors.⁴⁵ Clinicians should pay particular attention to patients with these conditions and close monitoring of coagulation profiles should be performed.⁴⁵

Treatment of Long-Acting Vitamin K Antagonist Overdoses

In patients with unintentional, small ingestions of long-acting VKAs, the risk of coagulopathy is low. Because it takes days to develop coagulopathy, most authors recommend supportive care only, although administration of activated charcoal is reasonable.^{147,266}

Treatment of a patient with a coagulopathy resulting from a long-acting anticoagulant overdose is essentially the same as the treatment of oral anticoagulant toxicity with certain exceptions. Although initial parenteral vitamin K₁ doses as high as 400 mg have been required for reversal,⁴² daily oral vitamin K₁ requirements may be in the range of 50 to 200 mg. Recent experience in both animals and humans suggests that parenteral vitamin K₁ therapy might not be required after initial stabilization (Antidotes in Depth: A15).^{41,327}

Long-acting VKAs are metabolized by the cytochrome P450 system.^{11,214} In a rat model, the duration of coagulopathy was shortened by administering phenobarbital, a CYP3A4 inducer.¹¹ Although phenobarbital has never been systematically studied in humans, this approach was used by several authors in isolated human cases of long-acting anticoagulant toxicity.^{42,141,180,285,309} These anecdotal reports suggest some improvement with phenobarbital therapy, but the risk of sedation in a patient who might be prone to bleeding complications would argue against this approach.

Patients with long-acting VKA overdose should be followed until their coagulation studies remain normal without treatment for several days. This usually requires daily or even twice-daily INR measurements until the INR is at the lower limit of the therapeutic range. Monitoring of serial INR measurements should allow for a gradual decrease in vitamin K₁ requirement over time. Periodic coagulation factor analysis (particularly factor VII), however, may provide an early clue to the resolution of toxicity.¹²⁹ The patient may require weeks to months of close observation for both psychiatric and medical management. Emphasis has been placed on determining a critical superwarfarin concentration below which anticoagulation does not occur.⁴² In one case report, brodifacoum was observed to follow zero-order elimination kinetics.⁴¹ If this type of toxicokinetics is consistent in the analysis of other long-acting VKAs, these laboratory measurements may prove more reliable than the current empiric end points of therapy.

Nonbleeding Complications of Vitamin K Antagonists

Warfarin therapy is associated with three nonhemorrhagic lesions of the skin: urticaria,²⁵¹ purple toe syndrome,⁹⁶ and warfarin skin necrosis.^{59,151,160,193,301} Although warfarin skin necrosis was once thought to be a rare and idiosyncratic reaction,^{151,160} more recent evidence suggests a link between this disorder and protein C deficiency.^{160,301} Protein C activation is also dependent on vitamin K.⁵⁶ Patients who are homozygotes for protein C deficiency have an increased incidence of thrombosis and embolic events, such that they often require long-term anticoagulant therapy.⁵⁶ Because the half-life of protein C is shorter than that of many of the vitamin K–dependent coagulation factors, protein C concentrations fall rapidly during the first hours of warfarin therapy. This results in an imbalance that actually favors coagulation, and skin necrosis results due to microvascular thrombosis in dermal vessels.^{193,301} Although warfarin skin necrosis is more common in patients with protein C deficiency, this disorder is also described in patients with protein S and AT deficiencies.⁵⁹ Unfortunately, these deficiencies are neither necessary nor sufficient to account for the incidence of warfarin necrosis.⁵⁹ If necrosis occurs, warfarin should be discontinued and heparin should be initiated to decrease thrombosis of postcapillary venules. Some patients may also require surgical débridement.²⁴⁶

The purple toe syndrome, in contrast to warfarin-induced skin necrosis, is presumed to result from small atheroemboli that are no longer adherent to their plaques by clot (Fig. 18–10).

A recently recognized form of warfarin toxicity is warfarin-related nephropathy (WRN). In patients with CKD an acute increase in the INR above 3 was associated with an increase in serum creatinine and accelerated reduction in kidney function. The etiology of the WRN has been attributed to acute tubular injury and glomerular bleeding, demonstrated by the finding of red blood cells filling Bowman's capsule and red blood cells casts obstructing glomeruli on specimens from kidney biopsies.^{39,40} Further studies that retrospectively reviewed kidney function in patients on long-term warfarin anticoagulation showed 33% of patients with CKD and 16.5% of patients without CKD developed WRN. WRN is associated with a mortality rate of 31.1%, a significant increase in risk compared to 18.9% in patients without WRN.³⁹

An additional major nonhemorrhagic complication of warfarin therapy is warfarin embryopathy. Most warfarin-induced fetal abnormalities occur during weeks 6 to 12 of gestation, but central nervous system (CNS) and ocular abnormalities can develop at any time during gestation (Chap. 31).^{121,274}

ANTITHROMBIN AGONISTS

Heparin

Conventional or unfractionated heparin is a heterogeneous group of molecules within the class of glycosaminoglycans.¹³⁸ The heparin precursor molecule is composed of long chains of mucopolysaccharides, a polypeptide, and carbohydrates. The main carbohydrate components of heparin molecules include uronic acids and amino sugars in polysaccharide chains. Heparin for pharmaceutical use is extracted from bovine lung tissue and porcine intestines.²⁵⁵

Heparin inhibits thrombosis by accelerating the binding of AT to thrombin (activated factor II) and other serine proteases involved in coagulation.^{185,241} Thus, factors IX to XII, kallikrein, and thrombin are inhibited. Heparin also affects plasminogen activator inhibitor, protein C inhibitor, and other components of coagulation. The therapeutic effect of heparin is usually measured through the activated PTT. The activated clotting time (ACT) may be more useful for monitoring large therapeutic doses or in the overdose situation.¹⁵⁹

Low-molecular-weight heparins (LMWHs) are 4000- to 6000-Da fractions obtained from conventional (unfractionated) heparin.¹⁰² As such, they share many of the pharmacologic and toxicologic properties of conventional heparin.³³ The various LMWHs (eg, nadroparin, enoxaparin, dalteparin) are prepared by different methods of depolymerization of heparin; consequently, they each differ to a certain extent regarding their pharmacokinetic properties and anticoagulant profiles. The major differences between LMWHs and conventional heparin are greater bioavailability, longer half-life, more predictable anticoagulation with fixed dosing, targeted activity against activated factor X, and less targeted activity against thrombin.^{33,102} As a result of this targeted factor X activity, LMWHs have minimal effect on the activated PTT, thereby eliminating either the need for, or the usefulness of monitoring. They are therefore administered on a fixed dose schedule. However, in certain instances (eg, patients with CKD, pregnancy, etc), monitoring of anti-factor Xa activity may be performed to assess adequacy of anticoagulation and to prevent the risk of bleeding.¹²² Controversy exists as to whether such testing is clinically necessary.³²

LMWHs have been investigated for prevention of thromboembolic disease after hip surgery and trauma, in patients with stroke or deep venous thrombosis, in pregnancy, and in other conditions where anticoagulation with heparin would otherwise be indicated (eg, at the onset of oral anticoagulation therapy). They have a minimal risk in pregnancy¹⁹⁷ because they do not cross the placenta,^{98,276} and they are therefore preferred for the treatment or prophylaxis of thromboembolic disease in pregnancy.²⁴⁰ Most studies demonstrate a lower incidence of embolization; however, there is still a trend toward increased bleeding.^{23,116,176} The PROTECT trial, which compared dalteparin and unfractionated heparin in terms of rates of proximal leg deep vein thrombosis, pulmonary emboli, and major bleeding in critically ill patients, found that patients randomized to the dalteparin group had statistically fewer pulmonary emboli. This particular study found no statistically significant differences in proximal DVT and major bleeding rates.²³²

Pharmacology

Because of the large size of heparin and negative charge, the molecule is unable to cross cellular membranes. These factors prevent oral administration, and heparin must be administered parenterally. Following parenteral administration, heparin remains in the intravascular compartment, in part bound to globulins, fibrinogen, and low-density lipoproteins, resulting in a volume of distribution of 0.06 L/kg in humans.^{93,216} Because of its rapid metabolism in the liver by a heparinase, heparin has a short duration of effect.¹⁸⁵ Although the half-life of elimination is dose dependent and ranges from 1 to 2.5 hours,^{185,192,216} the duration of anticoagulant effect is usually reported as 1 to 3 hours.¹⁸⁵ Dosing errors or drug interactions with thrombolytics, antiplatelet drugs, or nonsteroidal antiinflammatory drugs may increase the risk of bleeding.¹²⁴ LMWHs are nearly 90% bioavailable following subcutaneous administration and have an elimination half-life of 3 to 6 hours.¹⁰⁶ Anti-factor Xa activity peaks between 3 and 5 hours after dosing.¹⁰⁶ LMWHs are renally eliminated and patients with stage 4 or 5 CKD are at increased risk of toxicity.³⁰² Although there are insufficient data guiding therapeutic LMWH dosing in patients with severe CKD, some advocate dose reduction to decrease the risk of bleeding. However, no dosage regimens are provided.¹¹⁷

Clinical Manifestations

Intentional overdoses with heparin are rare.¹⁹⁰ Most reported cases involve iatrogenic toxicity in hospitalized patients.^{105,110,190,219,254} These cases have involved the administration of large amounts of heparin as a consequence of misidentification of heparin vials, during the process of flushing intravenous lines, and secondary to intravenous pump malfunction. Significant bleeding complications occurred in several cases, including at least one fatality.¹⁰⁵ However, intentional overdoses of LMWHs are reported, although none of them have been fatal.^{43,203}

Similar adverse effects to unfractionated heparin are also reported with LMWHs and include epidural/spinal hematoma, intrahepatic bleeding,¹³² abdominal wall hematomas,⁷ psoas hematoma after lumbar plexus block,¹⁵⁰ and

intracranial bleeding in patients with CNS malignancy.⁷⁷ While the above complications were all reported in patients who received the LMWH enoxaparin, there are no data to suggest differing toxicities among LMWHs.

Diagnostic Testing

For therapeutic anticoagulation, the effect of heparin is usually monitored with aPTT. Most hospitals have heparin nomograms that recommend heparin dose alterations based on aPTT, although these nomograms need to be individualized by each hospital due to the variation expected from the particular aPTT reagent and laboratory technology employed. For patients undergoing cardiovascular procedures, activated clotting time may be used to monitor these patients since they require higher-dose heparin.¹⁰⁶ More recently, an anti-Xa assay specific for heparin has been FDA approved.

In patients with heparin resistance, where extremely high doses of heparin are required to accomplish a therapeutic aPTT, anti-Xa levels may be used to guide heparin dosing. Despite lower heparin dosing and subtherapeutic aPTTs, patients monitored with anti-Xa activity had similar rates of recurrent thromboembolism and bleeding when compared to the patients who were given high-dose heparin to maintain therapeutic aPTTs in a prospectively collected randomized control trial.¹⁷⁷

LMWHs are usually administered at fixed doses for VTE prophylaxis or at weight-based doses for VTE treatment. Laboratory monitoring is not done unless patients are pregnant, have CKD, or are obese. In these cases, anti-factor Xa activity is measured, with target ranges varying based on agent and dosing regimen.¹⁰⁶ In patients without the aforementioned risk factors, monitoring and dose adjustment are of no benefit when compared to fixed-dose regimens of LMWH.³ In addition, several studies have shown no correlation between anti-factor Xa level activity and bleeding propensity.^{13,171,305}

Treatment

After stabilization of the airway and breathing and circulation are assured, the physician should be prepared to replace blood loss and reverse the coagulopathy, if indicated. Because of the relatively short duration of action of heparin, observation alone might be indicated if significant bleeding has not occurred. For the patient requiring anticoagulation, serial aPTT determinations will indicate when it is safe to resume therapy. If significant bleeding occurs, either removal of the heparin or reversal of its anticoagulant effect is indicated. Because heparin has a very small volume of distribution, it can be effectively removed by exchange transfusion.²⁵⁴ Although this technique has been used successfully in neonates, it is not generally applicable to older children and adults.

When severe bleeding occurs, unfractionated heparin may be effectively neutralized by protamine sulfate⁵ (Table 60–1). Protamine is a low-molecular-weight protein found in the sperm and testes of salmon, which forms ionic bonds with heparin and renders it devoid of anticoagulant activity.¹⁸⁵ One milligram of protamine sulfate injected intravenously neutralizes 100 units of unfractionated heparin.¹⁸⁵ The dose of protamine should be calculated from the dose of heparin administered if known and assuming the approximate half-life of heparin to be 60 to 90 minutes; the amount of protamine should not exceed the amount of heparin expected to be found intravascularly at the time of infusion. As with other foreign proteins, protamine administration is associated with numerous adverse effects such as hypotension, bradycardia, and allergic reactions. Because approximately 0.2% of patients receiving protamine experience anaphylaxis, a complication that carries a 30% mortality rate, most authors recommend that protamine be reserved for patients with life-threatening bleeding (Antidotes in Depth: A16).¹³² It should also be noted that excess protamine administration may result in paradoxical anticoagulation.

Because of the severe adverse effects associated with protamine, research has focused on safer methods to reverse heparin anticoagulation. These agents include heparinase,¹⁹⁹ synthetic protamine variants,^{303,304} and platelet factor 4. These therapies are not widely available, and their efficacy and safety have not been established.

If life-threatening bleeding occurs following LMWH administration, patients should also be treated with protamine. Several studies suggest that protamine partially reverses LMWHs such as enoxaparin, dalteparin, and tinzaparin. In one case report of a 10-fold dosing error of enoxaparin, protamine effectively reversed the anticoagulant effects.³²¹ In a series of 14 bleeding patients given protamine to reverse LMWH, bleeding ceased in two-thirds of the patients. These data, however, are complicated by repeat dosing of protamine as well as administration of other procoagulant antidotes such as clotting factors and vitamin K in a subset of patients. In addition, patients received protamine between 30 minutes and 48 hours after their last dose of LMWH.²⁹⁶ Current recommendations are to administer 1 mg protamine per 100 anti-factor Xa units, where 1 mg enoxaparin equals 100 anti-factor Xa units if within 8 hours of the LMWH administration.⁷⁹ A second dose of 0.5 mg protamine per 100 anti-factor Xa units should be administered if bleeding continues. If more than 8 hours has elapsed, a smaller dose of protamine can be administered.¹⁰⁶ The appropriate dosages for protamine are described in detail in the Antidotes in Depth: A16. The newer experimental protamine variants appear to be effective against LMWHs but are not yet available.^{303,304} Interestingly, there is one case report of recombinant activated factor VII (rfVIIa) reversing

the effects of LMWH in the setting of postoperative acute kidney injury (AKI),^{75,200,210} and there is also a single case report demonstrating efficacy at reversing severe bleeding caused by enoxaparin.¹³⁴

NONBLEEDING COMPLICATIONS

Postoperative thrombocytopenia that occurs in the first 1 or 2 days following surgery usually results from platelet consumption. This early fall in platelet count tends to cause concern for a drug-induced thrombocytopenia called heparin-induced thrombocytopenia (HIT) because postoperative venous thromboembolism (VTE) prophylaxis with heparin is usually started simultaneously.³⁰⁸ However, postoperative thrombocytopenia usually improves by the third postoperative day, distinguishing itself from HIT, which typically occurs between days 5 and 10 following heparin initiation. In patients who were previously treated with heparin, HIT-related events can occur within 24 hours post reexposure.¹⁷⁸

HIT affects up to 5% of patients receiving heparin.^{178,308} Heparin stimulates platelets to release platelet factor 4, which subsequently complexes with heparin to provoke an IgG response, causing platelet aggregation and thrombocytopenia.^{9,329} A more severe form of thrombocytopenia, heparin-induced thrombocytopenia and thrombosis syndrome (HITT; formerly known as HIT-2 or the white clot syndrome), occurs in up to 55% of patients with untreated HIT.¹⁷⁸ The antibodies against the heparin–platelet factor 4 complex activate platelets, which may lead to platelet–fibrin thrombotic events.^{9,329}

Patients may present with either hemorrhagic or thromboembolic complications. LMWH is also associated with thrombocytopenia (isolated HIT), and less frequently with HITT.¹⁷⁸ Consequently, once HITT occurs, LMWH is contraindicated.¹⁷⁸ Treatment of HIT includes discontinuation of heparin or LMWH and immediate use of alternative anticoagulant such as lepirudin, argatroban, or danaparoid.^{52,178} In addition to HIT and HITT, necrotizing skin lesions²²⁷ and hyperkalemia from aldosterone suppression²¹⁷ also rarely occur in patients receiving heparin therapy. These patients should not receive heparin or LMWH again, not even in low doses to maintain venous patency.

Some additional complications of heparin use include osteoporosis, which mostly occurs in patients on long-term therapy with unfractionated heparin.¹³³ A small percentage of these patients may develop bone fractures if treated continuously for more than 3 months. Data for LMWHs are limited, and the incidence of osteoporosis may be less compared with unfractionated heparin.¹³³ In 2008, an outbreak of adverse events was linked to heparin contaminated with over sulfated chondroitin sulfate.¹⁸¹ The contaminated heparin, which was found in at least 10 countries, originated in China.²⁹ Many patients developed anaphylactoid-type reactions with at least 100 reported deaths.¹⁸¹

DIRECT THROMBIN INHIBITORS

Hirudin and its congeners (lepirudin and desirudin) are used in acute coronary syndrome, the prevention of thromboembolic disease, and in patients with HIT(T).^{27,250,256} Desirudin appears to be at least as effective as unfractionated heparin and without an increased risk of bleeding or thrombocytopenia. However, in the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) IIb study of patients with unstable angina/non-Q wave myocardial infarction, there was an increase in the number of blood transfusions in patients who received desirudin as compared with those who received heparin.²⁶² This increased risk of bleeding as compared to heparin has caused desirudin to fall out of favor. Instead bivalirudin and argatroban tend to be used more often, especially in the setting of HIT(T). In fact, initial studies using bivalirudin during coronary artery angioplasty for unstable or postinfarction angina showed that it is a safe substitute for heparin with lower bleeding rates.²⁷ Unfortunately, all of these thrombin inhibitors are short acting and require parenteral administration.

Because of the potential therapeutic limitations of warfarin (eg, dosing, risk of bleeding, narrow therapeutic window), novel oral anticoagulants have been developed with directed activity against specific clotting factors. The proposed benefits of these medications include the convenience of fixed dosing and avoidance of close therapeutic monitoring. Ximelagatran was one of the first direct thrombin inhibitors that appeared to be as effective as warfarin in the treatment of stroke prevention, nonvalvular atrial fibrillation, and deep venous thrombosis.¹²⁸ Ximelagatran had many advantages over warfarin, including rapidity of onset, fixed dosing, stable absorption, decreased risk of drug interactions, and lack of necessity for therapeutic monitoring.¹²⁸ However, in 2006, drug manufacturers abandoned ximelagatran after noticing a high rate of hepatic failure. Countries that had approved ximelagatran withdrew the medication from the market.

Subsequently, dabigatran was approved for systemic anticoagulation in patients with nonvalvular atrial fibrillation in the United States and many other countries. Some countries also label an indication for dabigatran use in VTE prophylaxis following elective knee or hip surgery. The Randomized Evaluation of Long Term Anticoagulant Therapy (RE-LY) trial demonstrated that dabigatran administration was associated with lower rates of systemic embolic events, with similar rates of bleeding, when compared to anticoagulation with warfarin.⁶³ However, subsequent evaluation of the data acquired from the RE-LY trial demonstrates that patients 75 years of age and older may have an increased risk of extracranial bleeding

when compared to those on warfarin.⁸⁶ In multiple noninferiority trials, dabigatran is as effective as enoxaparin in reducing VTE without increasing bleeding risk after select joint replacement.^{89,90}

Pharmacology

Thrombin has four separate binding sites, each of which is specific for substrate, inhibitor, or cofactors.²⁸⁷ Bivalent direct thrombin inhibitors, such as hirudin and bivalirudin, bind the active site and one of two exosites (binding sites outside of the active site), whereas univalent direct thrombin inhibitors, such as dabigatran, bind just the active site⁷⁶ (Fig. 60–3). By directly inhibiting thrombin, anticoagulation is possible without the need for antithrombin.²⁵⁶ In addition, inhibiting thrombin also inhibits platelet activation because thrombin is a potent and direct-acting platelet activator. Unlike heparin, direct thrombin inhibitors are able to enter clots and inhibit clot-bound thrombin due to their small size, offering the distinct advantage of restricting further thrombus formation.

FIGURE 60–3. Thrombin has four separate binding sites. Each site is specific for substrate, inhibitor, or cofactors. Bivalent direct thrombin inhibitors, such as hirudin and bivalirudin, bind the active site and one of two exosites. Univalent direct thrombin inhibitors, such as dabigatran, bind only the active site.

Desirudin, bivalirudin, and argatroban are all administered parenterally. Desirudin is given as subcutaneous injections for VTE prophylaxis. While the dosing for desirudin is 15 mg as a subcutaneous injection every 12 hours, this dose may need to be decreased or stopped in patients with stage 3 or greater CKD. In addition, patients who have been treated with the hirudins may develop antibodies, creating the potential for anaphylaxis with repeat dosing.¹⁰⁶ Bivalirudin is also an analogue of hirudin. It is used in patients with HIT(T) who require cardiac catheterization or cardiopulmonary bypass surgery.¹⁰⁶ Argatroban binds noncovalently to the active site of thrombin to function as a competitive inhibitor.¹⁰⁶ It is metabolized by CYP3A4/5 in the liver and is particularly useful in patients with CKD.¹⁰⁶

Dabigatran is orally administered as dabigatran etexilate. This prodrug has no anticoagulant properties, and serum esterase converts it to dabigatran, the active drug.²⁶⁹ At therapeutic doses, peak concentrations occur in 2 hours (Table 60–3). Approximately 35% of dabigatran is protein bound; 85% is eliminated renally, with 78% of it eliminated within the first 24 hours. Its mean terminal half-life is approximately 8 to 12 hours.²⁸ Contraindications to dabigatran are active pathological bleeding or a hypersensitivity reaction to dabigatran. While there are theoretical interactions with other drugs that are p-glycoprotein inducers or inhibitors, the package insert does not recommend any dose adjustment for patients taking medications that are known p-glycoprotein inducers or inhibitors.

TABLE 60–3. Pharmacology of Oral Antithrombotics^a

	<i>Warfarin</i>	<i>Dabigatran (Pradaxa)</i>	<i>Rivaroxaban (Xarelto)</i>	<i>Apixaban (Eliquis)</i>
T _{max} (hours)	3	2	3	1–3
t _{1/2} (hours) ^a	35	8–12	5–13	8–15
Protein binding	97%	35%	>90%	87%
Metabolism and elimination	Hepatic metabolites (primarily CYP1A2, CYP3A4, and CYP2C9) excreted via renal and biliary systems	80%–85% renal; 15%–20% biliary	33% renal (unchanged); 33% renal metabolite; 33% hepatic metabolite	25% renal; 55% fecal, 15% hepatic metabolite

^aAntithrombotic metabolism and t_{1/2} may be altered by a number of factors such as diet, genetic polymorphisms, and kidney disease.

Clinical Manifestations

Intentional overdoses with the direct thrombin inhibitors are rare events. Although there are reports of patients who develop significant coagulopathy following unintentional ingestion of excess dabigatran,^{49,326} the more common scenario is that patients become overanticoagulated due to improper dosing in patients with CKD or failure to adjust dosing in patients who develop AKI. In general, the parenterally administered medications have short elimination half-lives, and iatrogenic medication administration errors, if recognized, may be less risky than those that are longer acting.

Dabigatran, the newest of the direct thrombin inhibitors, is orally administered with a longer duration of action. Since its approval in 2010, bleeding as a complication of therapy remains a serious risk, there is no specific reversal xenobiotic. In 2011, the FDA released an advisory announcing that they were reviewing postmarketing reports of serious bleeding associated with dabigatran use. In addition, dabigatran has led the list of fatalities reported to the MedWatch system. There are many published case reports of patients bleeding while anticoagulated with dabigatran. Patients may have been subjected to increased risk of bleeding with risk factors such as increased age or CKD. In New Zealand and Australia, a significant number of bleeding events, including intracranial bleeding, gastrointestinal bleeding, hematuria, and hemoptysis, were reported in the period immediately following the approval of the medication. Up to 25% of the reports in this series involved errors in prescribing practices.¹²³ In particular, off-label use of dabigatran for anticoagulation in the setting of mechanical heart valves has led to valve thrombosis.^{54,231} Cardiac tamponade from hemopericardium, fatal epistaxis, serious gastrointestinal bleeding, postoperative bleeding complications, and intracranial bleeding are all reported.^{19,50,83,264,286} In addition, clinicians have expressed difficulties in treating traumatized patients with bleeding while anticoagulated with dabigatran.⁶⁶

Furthermore, several questions regarding other adverse effects related to dabigatran use have been raised. A meta-analysis comparing patients anticoagulated with dabigatran versus warfarin, enoxaparin, or placebo showed higher rates of myocardial infarction or acute coronary syndrome.²⁹⁰ In addition, though prior trials have implied that discontinuation of dabigatran does not cause rebound thrombosis, the authors of anecdotal reports of thrombotic events after cessation of dabigatran anticoagulation have questioned whether thrombosis is due to rebound or just sequelae from underlying hypercoagulability or illness.²⁸³

Laboratory Assessment

Monitoring the anticoagulant effect in the setting of direct thrombin inhibitor use is complex. For bivalirudin and argatroban, serial aPTT measurements are commonly used to estimate the degree of anticoagulation.¹⁰⁶ Admittedly, the aPTT is not a good test, since the degree of anticoagulation does not follow a linear relationship. This is particularly emphasized with dabigatran, the most recently developed direct thrombin inhibitor. For example, the aPTT increases at higher dabigatran concentrations, but relationship is nonlinear, with the aPTT plateauing at dabigatran concentrations greater than 200 ng/mL.²⁹⁵ Furthermore, the PT and INR may be elevated, but they do not correlate with the anticoagulant effect of dabigatran.^{270,295} Dilute thrombin time (dTT) and ecarin clotting time (ECT) are proposed as more accurate reflections of the anticoagulation effect.²⁹⁵ ECT is a laboratory assay that uses ecarin, a derivative of saw-scaled viper venom, as the reagent to activate prothrombin. Although some hospitals are able to obtain a TT in a clinically relevant time, the dTT and the ECT are usually unavailable.

Treatment of Direct Thrombin Inhibitor–Induced Coagulopathy

The direct thrombin inhibitors currently have no reversal agent. Limited data are available regarding toxicity of these xenobiotics. Although overdose of argatroban was successfully treated with FFP in one case report,³²⁸ the orally administered dabigatran has a significantly longer half-life compared to the older parenteral direct thrombin inhibitors. In the event of an acute ingestion of dabigatran, AC is indicated based on data from an in vitro model.²⁹⁴ The manufacturer suggests several strategies to treat patients with significant bleeding while anticoagulated with dabigatran. Transfusion of red blood cells and FFP along with supportive care is the mainstay of treatment (Table 60–1). Use of rFVIIa, PCC, and hemodialysis should be considered, but this is incompletely studied. In a murine study of dabigatran, collagenase-induced intracranial hematoma expansion was inhibited in a dose-dependent fashion by PCC with the best results at 100 units/kg, the equivalent of 200% factor replacement. In the same study, high-dose PCC decreased but did not normalize the tail vein bleeding time. rFVIIa was ineffective in limiting intracranial hematoma volume, while FFP limited intracranial hematoma size in the mice that were given a lower dose of dabigatran.³³⁰

However, conclusions drawn from murine studies should be limited when treating humans. First, the hemostatic therapies used in these murine experiments are human-derived, and cross-species effects cannot be predicted. Second, these mice had prolongation of their tail vein bleeding times, but dabigatran at therapeutic doses does not change bleeding time in humans.¹⁴⁴ Another study done in healthy humans found that aPTT, endogenous thrombin potential lag time, thrombin time, and ECT did not decrease with the administration of four-factor PCC.⁸⁴

Activated prothrombin complex concentrates (aPCC) contain factors II, VII, IX, and X in inactive and activated forms. The only product available in the United States is factor eight inhibitor bypassing activity (FEIBA). One ex-vivo study showed that after a single dose of dabigatran in healthy volunteers, FEIBA decreased endogenous thrombin potential and lag time while thrombin generation increased in a dose dependent fashion. In a murine study, aPCC reduced bleeding time at low doses. Unfortunately, at high doses, this effect was reduced.³³⁵

Hemodialysis remains a controversial intervention. A single study showed that after a subtherapeutic dose of dabigatran in patients with stage 5 CKD, the extraction ratios were 62% and 68% at 2 and 4 hours after the initiation of hemodialysis.²⁷¹ Although this suggests that dabigatran can be removed from the serum, it is unclear if hemodialysis can be safely performed in patients actively bleeding. The degree of anticoagulation in relation to a serum dabigatran concentration is unknown. Additionally, the possibility of rebound concentrations from redistribution following hemodialysis was not investigated and is a concern due to its high mean apparent volume of distribution (1160–5040 L) during the terminal phase.^{270,271} Several published case reports demonstrated significant drug rebound following hemodialysis in bleeding patients, sometimes up to 87% of the initial dabigatran concentration within 2 hours after the cessation of hemodialysis.^{48,49,264} In one case, posthemodialysis drug rebound was incompletely evaluated in an overdosed patient with pulmonary hemorrhage. Dabigatran concentrations at the beginning of hemodialysis (1100 ng/mL) were more than eight times the peak serum concentrations expected for patients taking the maximum daily dose. Although hemodialysis was able to decrease the serum dabigatran concentration to 18 ng/mL over 4 hours, it rebounded to 100 ng/mL just 20 minutes after cessation of dialysis. However, during hemodialysis, the patient's bleeding ceased, and he survived to discharge.⁴⁹ In other case reports, hemodialysis was not effective in stopping bleeding, and despite massive transfusion of red blood cells, FFP, and platelets, deaths from exsanguination occurred. In some cases, a repeat hemodialysis session or continuous venovenous hemodiafiltration was performed in anticipation of posthemodialysis rebound. While they were successful in decreasing serum dabigatran concentrations, they did not normalize the aPTT or the TT.²⁶⁴

A monoclonal antibody targeting dabigatran is being developed for use in patients requiring rapid reversal of anticoagulation.^{292,293} Its structure has an affinity for dabigatran that is over 350 times that for thrombin.²⁴⁹ Rat studies show that administration of this dabigatran-specific monoclonal antibody rapidly normalizes the aPTT and TT in rats pre-treated with dabigatran.²⁴⁹ In addition, in vitro studies using human and rat plasma show that the antidote reverses the effect of dabigatran as measured by a battery of functional clotting assays, including clotting time.²⁴⁹

Until approval of a definitive antidote, reversal of coagulopathy should be attempted with PCC at an initial dose of 25 units/kg. The effect of PCC should be maximal immediately after administration. Repeat dosing up to a total of 100 units/kg may be necessary in cases of life-threatening bleeding, with the understanding that the risk of thrombosis is unknown but real. Hemodialysis should be attempted in patients suspected of having extremely supratherapeutic serum dabigatran concentrations, if placement of a large bore catheter and hemodialysis is not prohibitive of definitive treatments such as operative intervention.

FACTOR Xa INHIBITORS

Rivaroxaban is the first orally active direct factor Xa inhibitor approved for VTE and stroke prophylaxis and treatment. Development of this class of drugs started in the 1980s after the discovery of antistasin, a naturally occurring factor Xa inhibitor from leeches. After screening a library of more than 200,000 compounds, a pharmaceutical company was able to

identify structures that inhibit factor Xa. After structure optimization, rivaroxaban was created for clinical trials.²²⁶

Numerous clinical trials have investigated the efficacy and safety of rivaroxaban. Initial studies evaluated efficacy for VTE prophylaxis following orthopedic joint replacements in noninferiority studies in comparison with LMWH.⁸⁷ After proving noninferiority, numerous trials compared rivaroxaban with either warfarin or LMWH for VTE prophylaxis and treatment, stroke prevention in nonvalvular atrial fibrillation, and prevention of cardiac events in acute coronary syndrome. Overall, rivaroxaban appears to have a lower associated rate of VTE. Although bleeding rates were higher in patients on rivaroxaban, the difference was not statistically significant.^{16,88,145,161,288} When compared to warfarin, rivaroxaban prevented more strokes or systemic thromboembolic events and significantly reduced the number of intracranial bleeds in patients with nonvalvular atrial fibrillation.²²⁴ The most recent published trial compared the use of rivaroxaban to placebo in patients with acute coronary syndrome. There was a significant risk reduction in death caused by any cardiac cause or stroke. However, rivaroxaban-treated patients had statistically significant increased rates of major and intracranial bleeding.¹⁹⁴

Apixaban is another oral factor Xa inhibitor that was recently approved by the FDA. Apixaban is approved for VTE prophylaxis in patients with atrial fibrillation. In Europe, it is used for the treatment of venous thromboembolic disease as well. Initial trials found that apixaban decreased the rate of VTE and all cause mortality following total knee replacement when compared to those patients anticoagulated with enoxaparin or warfarin. However, the overall bleeding rates were higher in those patients treated with apixaban.¹⁶² Subsequent studies evaluating the use of apixaban for VTE prophylaxis after hip or knee replacement showed lower rates of VTE and lower rates of bleeding when compared to anticoagulation with enoxaparin.^{163,164} Further studies show that in patients with atrial fibrillation unsuitable for anticoagulation with VKAs, apixaban significantly decreased the rate of stroke or systemic embolism when compared to anticoagulation with aspirin. In this study group, the rates of bleeding, intracranial bleeding, and mortality were all lower in the apixaban treated group.⁶² Similarly, patients anticoagulated with apixaban for atrial fibrillation had decreased rates of stroke, decreased bleeding rates, and lower mortality rates compared to those treated with warfarin.¹¹⁴ However, concomitant use of apixaban with aspirin or aspirin plus ADP-receptor antagonists (eg, clopidogrel) demonstrated increased rates of major bleeding without any reduction in ischemic events. Fatal bleeding and intracranial bleeding were significantly higher in the group that received apixaban.²

In trials comparing apixaban with enoxaparin, apixaban had similar or superior efficacy in preventing VTE following knee and hip surgeries. In addition, bleeding rates were lower in the group receiving apixaban.^{161,163,164} On the other hand, a trial comparing treatments for VTE prophylaxis in medical patients found lower DVT rates in patients treated with apixaban when compared to those treated with enoxaparin. However, rates of major bleeding were significantly higher in the apixaban group.¹¹² In trials investigating the use of apixaban in patients with recent acute coronary syndrome, excess bleeding caused early cessation of trials; however, most patients were concurrently treated with dual antiplatelet therapy.^{2,8}

There is an ever-growing list of factor Xa inhibitors on the horizon. Betrixaban, edoxaban, otamixaban, and TAK-442 are examples of synthetic factor Xa inhibitors in various stages of evaluation for therapeutic use.^{61,198,243,312}

Pharmacology

The factor Xa inhibitors are ideal anticoagulants as their site of action is the intersection of the intrinsic and extrinsic pathways, preventing thrombin activation.⁴⁴ These synthetic drugs reversibly inhibit factor Xa without any cofactor requirements. Some believe that this class of anticoagulants is safer than the direct thrombin inhibitors since they do not completely neutralize thrombin.

Rivaroxaban and apixaban selectively bind free and clot-bound factor Xa without inhibiting related serine proteases, including thrombin, trypsin, plasmin, or other activated clotting factors.⁹¹ In addition, rivaroxaban and apixaban inhibit tissue factor or collagen-induced thrombin formation. In vitro, the factor Xa inhibitors hinder tissue factor–induced platelet aggregation.^{91,325} Rivaroxaban does not directly inhibit platelet aggregation, and concomitant aspirin use does not affect the pharmacokinetics or safety of rivaroxaban in healthy human studies.^{44,91,154}

Rivaroxaban has an oral bioavailability of approximately 80%.³¹³ Inhibition of factor Xa peaks approximately 3 hours after administration of the rivaroxaban. This inhibition lasts for approximately 12 hours.¹⁵⁶ However, kidney or liver disease may lengthen its duration of action (Table 60–3). Dosing varies by indication and kidney function. Postorthopedic prophylaxis starts at 10 mg daily, while treatment of deep venous thrombosis or pulmonary embolus is between 15 and 20 mg twice daily. For VTE prophylaxis for nonvalvular atrial fibrillation, the dose is 20 mg daily. The manufacturer provides recommended dose adjustments for each indication based on kidney function.

Approximately one-third of rivaroxaban is eliminated unchanged by the kidneys while one-third is metabolized to inactive form and excreted by the kidney. The remaining one-third is metabolized by the CYP3A4-dependent and –independent pathways in the liver and then excreted fecally. Concomitant use of CYP3A4 inhibitors or p-glycoprotein inhibitors is contraindicated due to increased risk of serum drug accumulation of up to 160%.^{127,313}

In addition, rivaroxaban may be a suitable anticoagulant alternative in patients with HIT(T) because in vitro studies do not show platelet aggregation or activation in the presence of HIT(T) antibodies or release of PF4 from platelets.³⁰⁶ Future studies proving efficacy and safety are needed before these xenobiotics can be recommended for use in patients with HIT(T).

In preclinical studies, the oral bioavailability of apixaban is approximately 66%. Apixaban is primarily distributed to the blood compartment and is approximately 87% protein bound.⁹¹ Peak serum concentrations occur between 1 and 3 hours postingestion. There are multiple elimination pathways, suggesting that patients with either renal or hepatic impairment may be able to tolerate apixaban well. Approximately 25% of apixaban is excreted in the urine, with the majority being excreted up to 24 hours after a single dose. The majority of apixaban is excreted fecally between 24 to 48 hours after ingestion.^{91,233} Simultaneous administration of strong CYP3A4 inhibitors is contraindicated with apixaban.

Apixaban was recently approved in the United States for stroke prevention in patients with nonvalvular atrial fibrillation. Dosing in clinical trials varied based on indication. For stroke prevention in patients with atrial fibrillation, apixaban is dosed at 5 mg twice daily. Clinical trials show favorable efficacy in comparison to warfarin and aspirin, with reduced stroke rates and similar occurrences of bleeding.^{62,114} In other countries, apixaban is approved for VTE prophylaxis, where it is dosed at 2.5 mg twice daily.

Clinical Manifestations

Bleeding is the most concerning consequence of the factor Xa inhibitors, even at therapeutic doses. A case report describes a 21 month-old girl who developed an INR of 3.5 approximately 12 hours after ingesting an unknown quantity of rivaroxaban. She did not suffer any hemorrhagic consequences.¹⁹⁶ Another case report describes a 58 year-old man taking 10 mg of rivaroxaban per day who developed prolonged rectal bleeding 31 days after initiating treatment for prophylaxis following hip replacement.³⁰

Diagnostic Testing

Some studies done in healthy volunteers show that rivaroxaban inhibits factor Xa activity and prolongs PT, aPTT, and LMWH activity in a dose-dependent fashion.^{155,156} Unfortunately, PT and aPTT are not reliable measures of the anticoagulant effect of rivaroxaban because results can widely vary depending on the reagent used. Thrombin generation assays are prolonged and endogenous thrombin potential is decreased. Unfortunately, these assays are not readily available in most medical centers. Chromogenic anti-factor Xa activity, on the other hand, has been shown to reliably measure rivaroxaban concentrations over a large range of concentrations.³³³

Studies investigating the effect of apixaban on hematologic laboratory studies are limited, but multiple in vitro studies show that aPTT and PT increase in a dose-dependent fashion. The HepTest, a newly developed clotting assay that measures anti-Xa and anti-IIa activity, correlates best with the antithrombotic effect of apixaban. Unfortunately, it is not widely available since it is not yet FDA approved.^{91,324}

Treatment of Factor Xa Inhibitor–Induced Coagulopathy

The factor Xa inhibitors have no definitive reversal agent. The factor Xa inhibitors are not well studied, and there are no trials that evaluate the efficacy of gastrointestinal decontamination. However, the administration of AC after an acute overdose is prudent because of the lack of a definitive reversal agent once coagulopathy develops (Table 60–1). A single human study evaluated the use of four-factor PCC in reversing patients given rivaroxaban 20 mg twice daily for 2.5 days. PT and endogenous thrombin rapidly normalized after administration of 50 units/kg of PCC.⁸⁴ Rivaroxaban-anticoagulated rabbits showed improvements in coagulation assays after treatment with PCC and rFVIIa. However, these agents were clinically ineffective in achieving hemostasis.¹¹¹ Due to its high protein binding, hemodialysis is unlikely to be an effective adjunct method to accelerate rivaroxaban removal.

Preliminary in vitro studies show that four-factor PCC may improve thrombin generation and coagulation parameters in blood aliquots treated with apixaban.⁹² However, there are no human studies with clinically relevant outcomes to support the use of PCC in factor Xa–associated bleeding.

While the half-lives of the factor Xa inhibitor are substantially shorter than that of warfarin, normalization of hemostasis due to drug clearance can still require more than 24 hours without intervention. During this time, supportive measures such as restoration of intravascular volume are helpful but do not correct the xenobiotic-induced coagulopathy. PCC at a starting dose of 25 units/kg appears to be the only antidote that may improve laboratory parameters immediately following infusion, but its effect on hemostasis is unknown. Regardless, in case of life threatening bleeding, PCC can be administered to attempt hemostasis, although further studies are needed to support this recommendation. Its peak effect should occur immediately after administration. In severe cases, repeat doses may need to be administered. The risk of thrombosis is unknown and should be weighed when administering PCC.

PENTASACCHARIDES

Pentasaccharides are synthetic anticoagulants that possess activity against factor Xa and are used for the prevention and treatment of VTE. Although other xenobiotics have been studied, fondaparinux is the only pentasaccharide currently available for clinical use.¹⁷³ The pentasaccharide binds to AT with an affinity higher than that of heparin facilitating the formation of the AT–factor Xa complex. Once this complex forms, the pentasaccharide dissociates and repeats the process.¹⁰⁶ Routine measurements of coagulation are not generally performed. When degree of anticoagulation needs to be assessed, the fondaparinux-specific anti-Xa assay is the most helpful. The pentasaccharides have long half-lives and have no reliable antidote if bleeding occurs; they do not bind to protamine.¹⁰⁶ Patients with stage 3 CKD should have their dose reduced 50%; fondaparinux is contraindicated in patients with stages 4 and 5 CKD.¹⁰⁶ No controlled trials are available yet, but rfVIIa may be effective for reversal, as demonstrated in one study of healthy volunteers.²⁵ In a case series of eight patients who received 90 µg/kg of rfVIIa for unstable bleeding, only 50% of patients had favorable outcomes. Anti-Xa activity remained unchanged, and none of the patients suffered any thrombotic complications. However, many of these patients were on other antithrombotics, including antiplatelet drugs.

ANTICOAGULANT APTAMERS

Aptamer anticoagulants are small nucleic acid molecules that are currently under development to target specific blood coagulation proteins.²¹¹ They are direct protein inhibitors and function similarly to monoclonal antibodies.²¹¹ Specific aptamers that are currently being studied include the anti–factor IX aptamer, the anti–activated protein C aptamer, and the anti–factor VIIa aptamer.¹¹³ These xenobiotics may have future clinical utility since their anticoagulant effects appear to be easier to control, and consequently safer, compared with the currently most used anticoagulants.

Although not yet approved, pegnivacogin is an RNA aptamer that inhibits factor IX and is undergoing human trials to evaluate its efficacy and safety. Numerous phase I trials are being conducted in healthy volunteers and patients with coronary artery disease.^{229,230} The effects of pegnivacogin mimic hemophilia B, also known as Christmas disease, which results in a tendency to bleed. By inhibiting factor IX, the conversion of factor X to factor Xa is inhibited.²⁹⁹ Previous studies have shown that approximately 1 mg/kg of pegnivacogin inhibits more than 99% of factor IX. Pharmacokinetic studies demonstrate a half-life of pegnivacogin to be approximately 100 hours and stable antithrombotic effects for 30 hours.^{228,229} While anticoagulated with pegnivacogin, the degree of anticoagulation can be monitored with aPTT as previous studies have demonstrated that the degree of factor IX inhibition correlates well with aPTT.²²⁹ Because this aptamer is a synthetically tailored nucleic acid sequence, its antidote is easily manufactured. By creating a complementary aptamer that possesses a nucleic acid sequence that binds to pegnivacogin through Watson-Crick base pairing, it can effectively neutralize the original xenobiotic by creating an inactive complex. In fact, pegnivacogin is being studied in conjunction with anivamersen, the complementary aptamer to pegnivacogin.²⁹⁸

FIBRINOLYTICS

The fibrinolytic system is designed to remove unwanted clots, while leaving those clots protecting sites of vascular injury intact. Plasminogen exists as a proenzyme that is converted to the active form, plasmin, by plasminogen activators.^{57,58} The actions of plasmin are nonspecific in that it degrades fibrin clots and also, some plasma proteins and coagulation factors.³¹¹ Inhibition of plasmin occurs through α_2 -antiplasmin.³¹¹ Tissue plasminogen activator (t-PA) is released from the endothelium and is under the inhibitory control of two inactivators known as tissue plasminogen activator inhibitors 1 and 2 (t-PAI-1 and t-PAI-2).^{57,58,206,311} Under physiological conditions, endogenous t-PA does not induce a lytic state because there is no fibrin to initiate the conversion of plasminogen to plasmin. However, exogenous t-PA administration results in supraphysiological concentrations that promote a lytic state.³¹¹

With their diverse indications in acute myocardial infarction, unstable angina, arterial and venous thrombosis and embolism, and cerebrovascular disease, the thrombolytics are commonly used.²⁰ The reader is referred to a number of reviews for specific indications and dosing regimens.^{65,166,223,265,311,318} Although all fibrinolytics enhance fibrinolysis, they differ in their specific sites of action and duration of effect. t-PA is produced by recombinant DNA technology, and it is clot-specific (ie, it does not increase fibrinolysis in the absence of a thrombus). Newer thrombolytics include reteplase and tenecteplase; they possess longer half-lives that facilitate administration via bolus dosing rather than infusion.³¹¹ On the other hand, streptokinase, urokinase, and anistreplase are not clot-specific. t-PA has the shortest half-life and duration of effect (5 minutes and 2 hours, respectively) and anistreplase the longest (90 minutes and 18 hours, respectively).^{223,265} Streptokinase has the additional risk of potential severe allergic reaction on rechallenge, limiting its use to once in a lifetime. In fact, streptokinase is no longer used in the United States.

Newer thrombolytics such as alteplase, tenecteplase, and desmoteplase are used in other countries or are

currently being evaluated for therapeutic use.¹⁸² These fibrinolytics have a longer half-life and may be administered via single or repeated bolus injections. They also have increased fibrin selectivity but no apparent improvement in mortality when compared to t-PA.¹⁴²

A number of contraindications preclude the use of fibrinolytics in order to decrease the risk of bleeding. Undesired bleeding occurs due to clot destruction at vascular compromised sites and destruction of coagulation factors from plasmin generation.³¹¹ As a result, patients with risk factors for bleeding, such as recent surgery or bleeding, known vascular lesions, or prior intracranial bleeding, are contraindications for fibrinolytic administration.

Clinical Manifestations

Although the incidence of bleeding requiring transfusion may be as high as 7.7% following high-dose (150 mg) t-PA and 4.4% following low-dose t-PA,⁶⁵ the incidence of intracranial bleeding with t-PA appears to be similar to the newer agents (alteplase, tenecteplase, reteplase, and lanoteplase).³⁰⁰ The addition of heparin to thrombolytic therapy increases the risk of bleeding. Reviews of multiple trials suggest that life-threatening events such as intracranial bleeding occur in 0.30% to 0.58% of patients receiving anistreplase, 0.42% to 0.73% of patients receiving alteplase, and 0.08% to 0.30% of patients receiving streptokinase.³¹⁸ Regardless of the thrombolytic used, the frequency of bleeding events is similar, with the exception that lanoteplase may have a decreased incidence of significant bleeding.⁷³

Treatment

Supportive care is indicated for patients with minor bleeding complications. However, for patients with significant bleeding, fibrinogen and coagulation factor replacement with cryoprecipitate, FFP, or PCC should be administered.²⁴⁸ If fibrinogen and factor replacement are ineffective, then antifibrinolytics such as aminocaproic acid and tranexamic acid should be considered (Table 60–1). These fibrinolytics prevent activation of plasmin by competing with fibrin to bind to plasminogen and plasmin. While a significant amount of fibrinolysis has already occurred, competitive inhibition of further plasmin-activated fibrinolysis may be helpful in cases of life-threatening bleeding. Aminocaproic acid is also able to prevent the binding of t-PA to fibrin. Not only can these agents prevent fibrinolysis, but they can also reverse excessive fibrinolysis,^{248,311} although it is not well studied in the setting of fibrinolytic therapy.

Aminocaproic acid can be given orally or intravenously. When administered intravenously, a loading dose of 4 to 5 g over one hour is followed by an infusion of 1–1.25 g/h with a maximum of 30 g given in 24 hours. The infusion should be stopped before 24 hours if the bleeding has ceased. Aminocaproic acid should not be given to patients with hematuria. These patients are at risk for developing obstructive AKI from ureteral clots that cannot be lysed. There are also rare reports of myopathy and muscle necrosis.³¹¹ Theoretically, aminocaproic acid could reverse bleeding following fibrinolytic therapy. However, there are no case reports or studies supporting its use in this situation.

Tranexamic acid can also be administered orally or intravenously. It is currently approved for the treatment of menorrhagia and is dosed at 1 g orally four times a day for four days.³¹¹ It is also used in hemophiliac patients undergoing cardiac surgery. However, recent studies have garnered significant attention for the use of tranexamic acid in patients with traumatic bleeding. The CRASH-2 study, a multicentered randomized controlled trial evaluating outcomes of patients receiving tranexamic acid with traumatic bleeding, found that infusion of 1 g over 10 minutes, followed by 1 g over 8 hours, resulted in a significant reduction in mortality. In addition, the risk of arterial thrombosis, as well as fatal and nonfatal thrombosis, was significantly reduced when compared to controls who received placebo.²³⁹ A case report describes the successful use of tranexamic acid in a patient who developed an intracranial bleeding following thrombolytic therapy. After receiving 1.675 g of intravenous tranexamic acid, repeat computed tomography and magnetic resonance imaging of his brain revealed no hematoma expansion, and he did not develop any thrombotic complications.¹⁰¹

Unfortunately aminocaproic acid and tranexamic acid are associated with generalized tonic-clonic seizures in up to 7.6% of patients. The precise mechanism of seizures is not known. In murine studies, competitive antagonism of glycine receptors is suggested. When the mice were treated with isoflurane and propofol, seizure activity ceased.¹⁶⁹

ANTIPLATELET DRUGS

Under normal conditions, vascular endothelium provides thromboregulators that prevent thrombus formation. When the endothelium becomes compromised, exposed collagen triggers two cascades of events to promote platelet aggregation. First, a tissue factor–mediated pathway indirectly activates platelets. Tissue factor, either from the damaged vessel wall or carried in the blood, complexes with factor VIIa and activates factor IX and the extrinsic pathway of the coagulation cascade. Thrombin then directly stimulates further platelet adhesion.¹⁰³ Secondly, when von Willebrand factor (vWF) adheres to the exposed endothelium, platelet glycoprotein Ib-V-IX binds to the vWF and anchors platelets to the site of vascular injury. In addition, platelet glycoprotein VI and Ia tether the platelets to exposed collagen^{70,103,158} (Fig. 60–4).

FIGURE 60–4. A schematic diagram of platelet aggregation. An injury to the endothelium results in initial platelet tethering by means of von Willebrand factor (vWF) and glycoprotein (GP) Ib-V-IX. Platelet GP VI and Ia tether the platelets to exposed collagen. GP IIb-IIIa is expressed on the surface of the platelets and allows platelet cross-linking with vWF bridging. TF = tissue factor.

After platelet adhesion, modulators such as adenosine diphosphate (ADP) and thromboxane A₂ (TXA₂) maintain platelet activation.^{70,103,311} Intracellular signaling results in the release of arachidonic acid (AA) via phospholipase A₂. Next, AA is converted into prostacyclin via cyclooxygenase-1 (COX-1) or cyclooxygenase-2 (COX-2). This stimulates the production of TXA₂, which further propagates platelet activation and aggregation^{70,139} (Fig. 60–5).

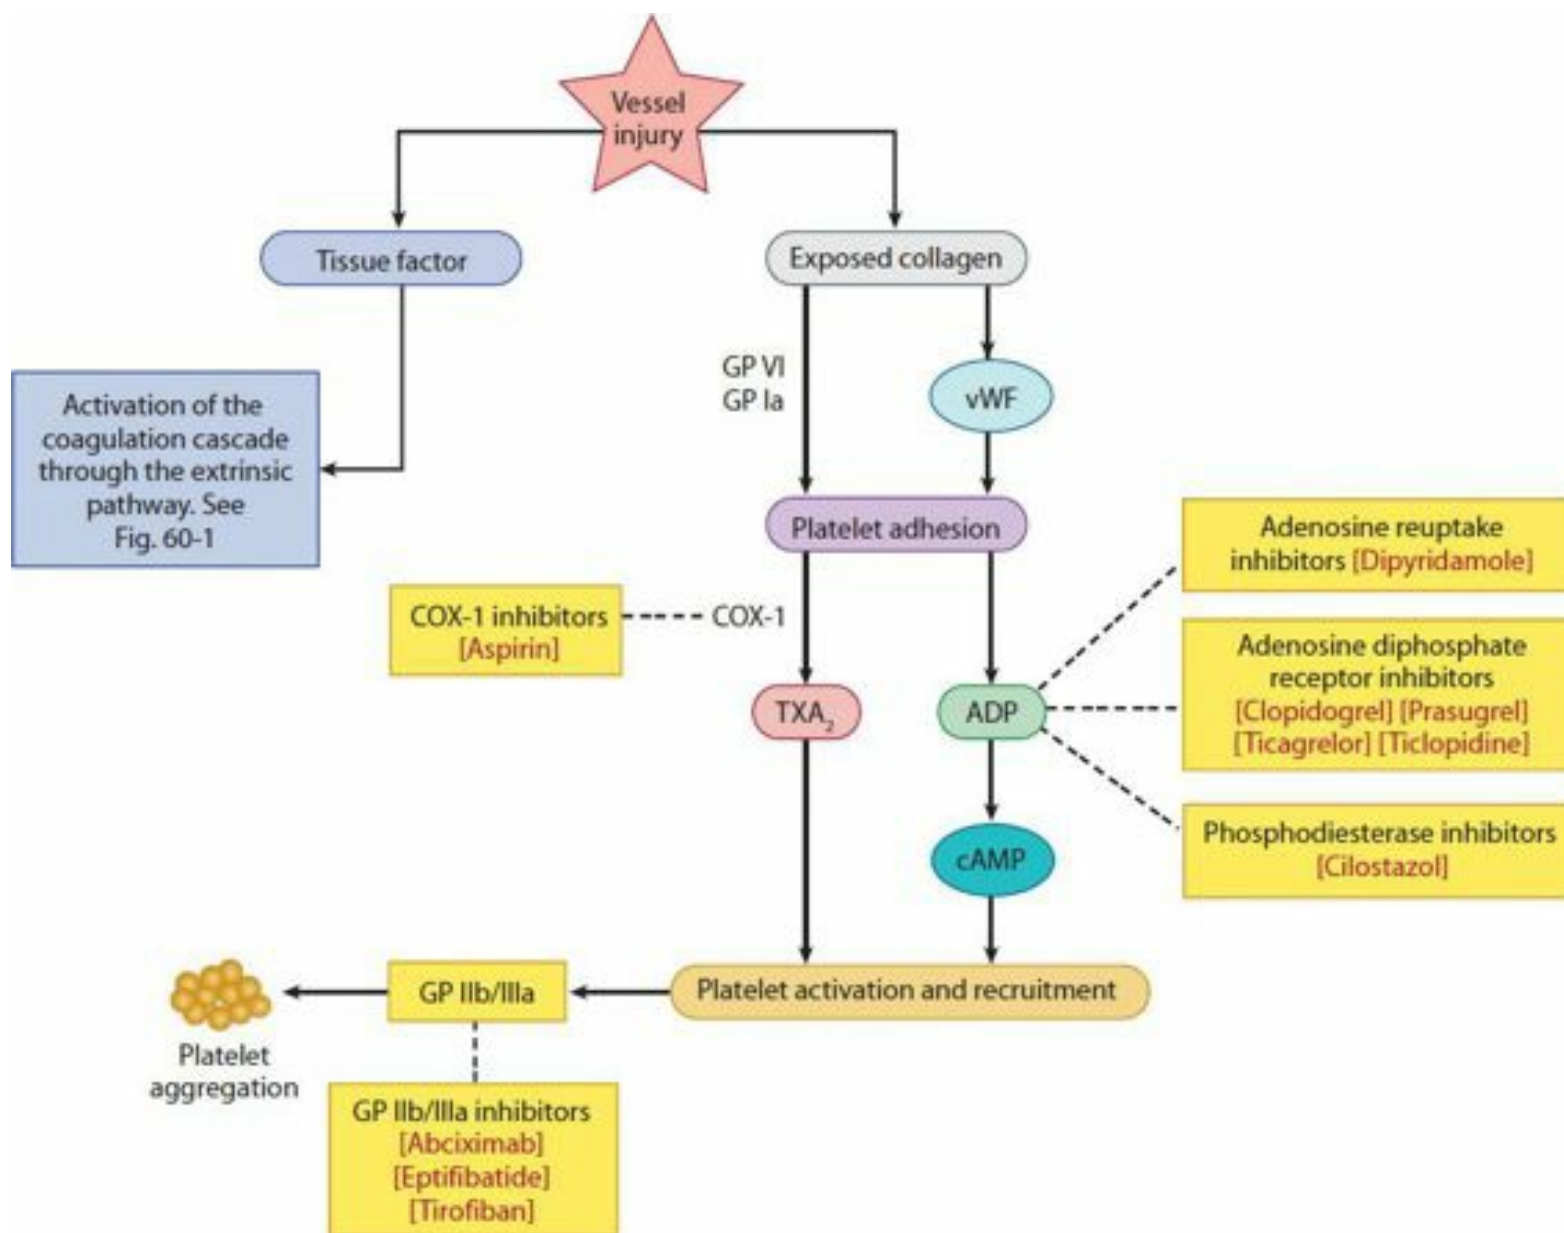

FIGURE 60–5. The antiplatelet drugs act in various stages of platelet aggregation. ADP = adenosine diphosphate; cAMP = cyclic adenosine monophosphate; COX-1 = cyclooxygenase 1; GP = glycoprotein; TXA₂ = thromboxane A₂; vWF = von Willebrand factor.

These mediators recruit more platelets to the area of vessel injury. Glycoprotein IIb-IIIa is expressed on the surface of the platelets and allows platelet cross-linking via this receptor with vWF acting as a bridge.^{70,103}

Thrombus formation perpetuates platelet aggregation and adhesion to the vessel wall. Platelet glycoprotein IIb-IIIa activation results in further thrombus formation by binding fibrinogen and vWF, essential to the linking of platelets.⁷⁰

Antiplatelet therapies aim to decrease platelet activation or aggregation by inhibiting one of the steps in the many pathways leading to glycoprotein IIb-IIIa activation of platelets.

CYCLOOXYGENASE INHIBITORS

Widespread use of aspirin as an antiplatelet drug is associated with significantly decreased vascular events. Aspirin acetylates the COX-1 enzyme, prevents substrate binding to the enzyme, and results in irreversible inhibition of TXA₂ generation. Daily low-dose aspirin can fully inhibit COX-1 function and subsequent platelet aggregation because platelets are unable to regenerate COX-1.⁸⁵ However, while aspirin irreversibly inhibits COX-2, larger doses of aspirin are required to decrease COX-2 mediated processes due to rapid synthesis of new COX-2.⁸⁵

Aspirin dosed between 75 and 150 mg showed the best odds reduction in preventing myocardial infarction and stroke when compared to other doses.^{6,85} In fact, high-dose aspirin may cause inhibition of other down regulators of platelet adhesion such as endothelium-derived prostacyclin. While effective in preventing vascular events, the risk of bleeding and gastrointestinal irritation must be considered. A randomized trial comparing low dose (70–150 mg/d) and standard-dose (300–325 mg/d) aspirin in patients with acute coronary syndrome, standard-dose aspirin conferred an increased risk of gastrointestinal bleeding without significant additional cardiovascular benefit.⁶⁹ However, even daily low-dose aspirin

resulted in a significantly increased risk of gastrointestinal bleeding when compared to nonaspirin use, but this risk is outweighed by the benefits of cardiovascular disease and stroke prevention.³¹⁰

CYCLIC ADENOSINE MONOPHOSPHATE MODULATORS

Phosphodiesterase Inhibitors

Cilostazol is a phosphodiesterase inhibitor marketed for the treatment of intermittent claudication secondary to peripheral vascular disease (PVD). By increasing cyclic adenosine monophosphate (cAMP), vasodilation is achieved by inhibiting myosin light-chain kinase, essential for smooth muscle contraction. Additionally, cAMP inhibits platelet aggregation. Small trials demonstrate that cilostazol improves walking distances, decreases arterial thrombosis, and improves rethrombosis rates in patients with PVD. In the Cilostazol for Prevention of Secondary Stroke (CSPS) study, cilostazol was not inferior to aspirin in preventing secondary stroke. However, due to its common gastrointestinal adverse effects and headache, a high rate of discontinuation precludes this xenobiotic from being more widely used.⁸⁵

Adenosine Reuptake Inhibitors

Dipyridamole has antiplatelet properties, although its mechanism of action is not completely known. Evidence suggests that by inhibiting degradation of cAMP and by blocking adenosine reuptake, intracellular cAMP accumulates and inhibits platelet aggregation.^{85,311} Dipyridamole may also have antiinflammatory properties by decreasing monocyte gene expression of chemokines.³¹⁷ Dipyridamole 200 mg is marketed alone or in combination with 25 mg of aspirin (Aggrenox).

Randomized studies demonstrate a significant reduction in stroke in high-risk patients taking dipyridamole with aspirin when compared with patients taking aspirin alone. However, many patients discontinue dipyridamole due to headache.^{78,120} Unfortunately, when compared to clopidogrel, dipyridamole and aspirin offer no improvement in stroke prevention and an increase in the risk of major bleeding.²⁴⁵

ADENOSINE DIPHOSPHATE RECEPTOR INHIBITORS

Platelets require stimulation of P2Y1 and P2Y12, adenosine diphosphate (ADP) receptors, to inhibit adenylyl cyclase. cAMP formation decreases as a result of the inhibition of adenylyl cyclase, and the platelet loses its ability to activate. Clopidogrel, prasugrel, ticagrelor, and ticlopidine are ADP receptor inhibitors. By increasing cAMP concentrations through inhibition of the P2Y12 receptor, these xenobiotics are able to inhibit platelet activation.^{85,311}

Ticlopidine is a first-generation ADP receptor inhibitor. It is typically taken orally at 250 mg twice daily. Despite its rapid absorption with peak plasma concentrations between 1 and 3 hours, peak platelet inhibition occurs one week after initiation. Two of the many metabolites are noted to have significantly stronger ADP receptor inhibitor activity than the parent drug. Ticlopidine does not confer an overall reduction of cardiovascular death, stroke, or myocardial infarction risk,¹⁰⁸ but coadministration with aspirin decreases stent thrombosis in some situations.¹⁷²

The relatively high risk of neutropenia as well as the risks of agranulocytosis, thrombocytopenia, and thrombocytopenic purpura–hemolytic uremic syndrome and the development of newer generation ADP receptor inhibitors has rendered ticlopidine nearly obsolete.^{85,311}

Clopidogrel irreversibly binds and inhibits ADP receptors. Maximal platelet inhibition is achieved between day 4 and 7 after initiation of maintenance doses but occurs 2 to 4 hours after a 600 mg loading dose.⁸⁵ Clopidogrel requires conversion via CYP2C19 to form its active metabolite. Up to one-third of patients are resistant to clopidogrel. Many of these patients possess a CYP2C19 genetic polymorphism that results in loss of function, and these patients have an increased risk of major cardiovascular adverse events, especially following coronary artery stenting.^{85,195} Similarly, concomitant administration of medications that inhibit numerous CYP enzymes may result in decreased efficacy. Further studies are required to determine if dosing modification may improve efficacy in preventing adverse vascular events.⁸⁵

Clopidogrel is dosed at 75 mg daily. It is commonly administered with aspirin as numerous studies, such as the CREDO, COMMIT, and CLARITY trials, have shown dual antiplatelet therapy to be beneficial in the reduction of vascular events.^{51,244,272} However, in the ACTIVE trials, warfarin was superior to dual antiplatelet therapy with aspirin and clopidogrel in preventing major vascular events.⁶⁰

The risk of bleeding remains a major concern associated with the use of clopidogrel, particularly in dual antiplatelet regimens. The ACTIVE A trials found an increased risk of major bleeding in patients with atrial fibrillation on clopidogrel and aspirin when compared to patients on aspirin alone.⁶⁴ In contrast, the COMMIT trial demonstrated no difference in major bleeding rates between study groups treated with and without clopidogrel.⁵¹

Another ADP receptor inhibitor, prasugrel similarly requires conversion to an active metabolite, which occurs within 30 minutes of dosing. CYP2C19 inhibition or concomitant proton pump inhibitor administration does not affect efficacy. A

head-to-head comparison of prasugrel and clopidogrel in patients undergoing coronary artery intervention found a decreased incidence of overall vascular adverse outcomes and death and stent thrombosis in patients on prasugrel but no improvement in overall morbidity, mortality, or bleeding events.^{85,323}

Ticagrelor is the newest of the ADP receptor inhibitors that exerts its effects by allosterically and reversibly inhibiting the ADP receptor. Absorption is rapid with peak plasma concentrations in approximately 2.5 hours.²⁸² Dosing of ticagrelor includes a loading dose of 180 mg, followed by a maintenance dose of 90 mg twice daily.

The PLATO trial demonstrated patients with acute coronary syndrome had a lower mortality rate from myocardial infarction and stroke when treated with ticagrelor versus clopidogrel. While overall bleeding rates were equivalent, nonprocedure bleeding, including fatal intracranial bleeding, was higher in the ticagrelor-treated group.³⁰⁸

GLYCOPROTEIN IIb-IIIa Inhibitors

Three glycoprotein IIb-IIIa inhibitors are available for use with patients with acute coronary syndromes. Abciximab is a monoclonal Fab antibody that binds the glycoprotein IIb-IIIa receptor. When administered with heparin and aspirin in patients undergoing coronary artery intervention, stent thrombosis, myocardial infarction, and mortality all decrease. Abciximab is administered as an intravenous bolus dose of 0.25 mg/kg is followed by an infusion on 0.125 mg/kg/min. The plasma half-life is short, with plasma concentrations becoming negligible approximately 30 minutes following cessation of the infusion. However, the Fab fragments bind to the platelets and inhibit platelet function for up to 24 hours.³¹¹

Eptifibatide is a synthetic glycoprotein IIb-IIIa inhibitor used in patients with acute coronary syndrome undergoing coronary artery interventions. Its molecular structure is based on snake venom disintegrin. An intravenous loading dose of 180 µg/kg is followed by an infusion of 2 µg/kg/min.³¹¹ Dosing in patients with CKD is unstudied, but there is a demonstrable increase in rates of bleeding in patients with a creatinine clearance less than 60 mL/min.²³⁴ Tirofiban also inhibits the glycoprotein IIb-IIIa receptor, and has similar clinical efficacy compared to eptifibatide.³¹¹

Up to 10% of patients treated with glycoprotein IIb-IIIa inhibitors have major bleeding events. Thrombocytopenia can also occur as a result of antigenic recognition of the xenobiotic-bound platelets.⁸⁵

A number of trials examining the efficacy and safety of the glycoprotein IIb-IIIa inhibitors have noted positive trends in decreasing predefined end points such as 30-day mortality, stent rethrombosis, and myocardial infarction. After evaluation of the combined data from multiple trials, the benefits of glycoprotein IIb-IIIa inhibitor therapy without early coronary artery revascularization are unclear when weighing the risks of bleeding. However, with early coronary artery revascularization, it is accepted that adding a glycoprotein IIb-IIIa inhibitor may be beneficial despite some concerns that the highest-risk patients truly benefit from this adjunctive therapy.^{72,85}

DEVELOPMENT OF NOVEL RECEPTOR AND ENZYME INHIBITORS

Recent pharmaceutical development has focused on inhibition of several key enzymes or receptors in platelet activation and aggregation. Thromboxane A₂ function can be inhibited by thromboxane A₂ synthase inhibitors or by antagonizing the thromboxane A₂ receptor. Clinical trials are currently underway to evaluate the efficacy of inhibiting protease-activated receptors, also called thrombin receptors.²⁸¹

Laboratory Assessment

Bleeding time is traditionally the most useful and widely available used to assess platelet function. However, its popularity has decreased because of its insensitivity, invasiveness, scarring, and high coefficient of variation. A variety of platelet function assays exist, but few are widely available. The gold standard assay, light transmission aggregometry is commonly used in specialty laboratories, but it does not reflect physiologic platelet adhesion or aggregation. Furthermore, this test is time-consuming and expensive. Several widely used tests to assess platelet function, such as flow cytometry and serum thromboxane B₂ assay, are available. Each of these tests has significant disadvantages such as being artifact-prone, expensive, nonspecific, or insensitive to select antiplatelet agents. In addition, extrapolating these results to determine a patient's risk of bleeding or thrombosis is not possible.¹²⁶

Management

When managing bleeding in patients taking antiplatelet xenobiotics, blood transfusion should be employed in patients with significant blood loss. However, transfusion of packed red blood cells will not increase platelet adhesion or aggregation. Unfortunately, the published literature that assesses interventions on bleeding patients maintained on antiplatelet xenobiotics is conflicting, and there is no clear consensus on appropriate reversal strategies and agents. The most widely evaluated intervention is platelet transfusion. The existing studies are small and mostly retrospective. Prospective studies

are biased by nonrandomization, specifically by the clinician ultimately deciding whether to transfuse the platelets. Many of these studies show that platelet transfusion is harmful and independently predict increased mortality and bleeding^{15,46} (Table 60–1).

Desmopressin is approved for the treatment of inherited defects of hemostasis and potentiates thrombosis by releasing vWF and factor VIII from the endothelium into the plasma. In these patients, complications such as arterial thrombosis and myocardial infarction have been reported after desmopressin administration.^{165,174} However, some proposed protocols for reversing antiplatelet xenobiotics in the setting of life-threatening bleeding include desmopressin. Most of these protocols are based on case reports since the majority of the studies have evaluated prophylactic desmopressin prior to surgery to prevent blood loss. A single study evaluated the administration of desmopressin on platelet aggregation and platelet activity in healthy volunteers given a single dose of clopidogrel. They found that platelet reactivity and platelet aggregation increased after desmopressin administration. There was no mention of adverse outcomes in any of the study subjects.¹⁷⁰ The risk of desmopressin-induced thrombosis in patients on antiplatelet xenobiotics is unknown; in patients taking antiplatelet medications for atherosclerosis, the risk of thrombosis may be greater.¹⁷⁰

In the case of abciximab, cessation of the infusion results in a rapid decrease in circulating antibodies. If severe bleeding occurs, platelet transfusion after discontinuation of the infusion is effective in restoring platelet activation and aggregation.³¹¹

In most cases, discontinuation of eptifibatide and tirofiban results in restoration of normal platelet function within hours. However, patients with renal dysfunction may suffer from prolonged platelet inhibition. Both of these xenobiotics are renally cleared, and some have suggested hemodialysis as a means to enhance clearance.²⁸⁰ While not formally studied, case reports of patients with protracted platelet inhibition in the setting of eptifibatide use and end stage CKD suggest that hemodialysis restores platelet aggregation capacity.²⁶⁷ Unlike abciximab, transfusion of platelets to these patients is believed to be ineffective in restoring platelet function. At therapeutic concentrations, the amount of these xenobiotics far outnumber the inhibited glycoprotein IIb-IIIa receptors by several orders of magnitude.²⁸⁰ Further studies are required to produce recommendations or guidelines for emergent reversal of antiplatelet xenobiotics to determine if any interventions are effective and offer a favorable risk to benefit profile.

SNAKE VENOMS

A detailed discussion of snake envenomations is found in Chap. 122 and Special Considerations: SC8; only a few specific issues are discussed here. Snake venoms may be composed of a vast number of complex proteins and peptides that interact with components of the human hemostatic system. In general, their functions may be thought of as being procoagulant, anticoagulant, fibrinolytic, vessel wall interactive, platelet active, or as protein inactivators. Additionally, they may more specifically also be classified based on their specific biologic activity; some of the various mechanisms include individual factor activation, inhibition of protein C and thrombin, fibrinogen degradation, platelet aggregation, and inhibition of serine protease inhibitors (SERPINS). Currently, there are more than 100 different snake venoms that affect the hemostatic system.^{136,137} Figure 60–1 is an overview of their multiple interactions with the coagulation and fibrinolytic systems.¹⁸⁹

Some of these venom proteins are being used as therapeutic agents for human diseases. Ancrod, a purified derivative of the Malayan pit viper, *Calloselasma rhodostoma* (formerly known as *Agkistrodon rhodostoma*), is therapeutically used because of its defibrinogenating property.¹⁸ The mechanism of action of ancrod and other similar agents is to link fibrinogen end-to-end and subsequently prevent cross-linking. It has been investigated in the treatment of deep venous thrombosis, myocardial infarction, pulmonary embolus, acute cerebrovascular thrombosis, HIT(T), and warfarin-related vascular complications. In a multicenter study of 500 patients with acute or progressing ischemic neurologic events, ancrod showed a favorable benefit-to-risk ratio compared with placebo.²⁵⁹ As expected, an increased risk of bleeding is observed; however, the risk appears to be less than that with thrombolytics.²⁵⁹ Monitoring of fibrinogen concentrations is essential to avoid potential complications, because no specific antidote exists. For envenomation of other snake venoms (such as from the Crotalinae family) that induce bleeding, antivenin treatment may be required.

SUMMARY

- The development of new antithrombotics and the increasing frequency of antithrombotic therapeutic use are associated with complications and adverse outcomes.
- A complete understanding of the normal mechanisms of coagulation, anticoagulation, and thrombolysis, combined with an understanding of the pharmacology of the xenobiotic and the clinical needs of the patient will allow the clinician to better choose among the complex therapies currently available.
- Supportive care is often adequate for certain complications associated with these therapies.
- More aggressive interventions and specific antidotes are necessary depending on the specific xenobiotic, particularly the newer factor inhibitors, and medical condition of the patient.

- Ongoing development of new antithrombotics will raise new challenges for clinicians as adverse outcomes and bleeding complications arise, and new antidotes will be developed to address these issues.
